During the latter part of Cox's engagement at Fox's Gap, General Hooker became severely engaged north of and at Turner's Gap. At daybreak of the 14th Hooker led the First corps from the Monocacy through Frederick and Middletown to Catocin Creek, where he halted at 1 P. M. for rest and coffee. Under instructions to attack the heights north of Turner's Gap and create a diversion in favor of Cox, he marched by the National road leading over Turner's Gap, turned to the right at Bolivar and marching nearly two miles halted and formed line at the eastern base of South Mountain, about 3.30 P. M.; Meade's division on the right, Hatch's on the left, with Rickett's in reserve. Gibbon's brigade of Hatch's division was left on the National road to advance directly into the gap. In Hooker's front the slopes to the crest of the mountain were very precipitous, rugged and partly wooded, bisected by gorges and small ravines, all presenting difficult ascent to an infantry force, even in the absence of a foe in front. At the time there was a veteran foe in front, well protected by rocks and trees and the numerous stone fences separating the fields. The position to be assaulted was held by the brigades of Rodes, Kemper, Garnett, Evans and Jenkins, all under command of Longstreet. Hooker was very deliberate in his preparations, and it was after 4 P. M. when his line moved forward. Hatch, on the left, made a laborious ascent of the mountain, with frequent halts to draw breath and reform his line; but driving in the Confederate skirmishers, he reached the wooded summit, and after severe fighting, in which he was wounded, succeeded in dislodging the Confederates from the stone fences behind which they had fought, and driving them back to another line. In this he had the assistance of a part of Rickett's division. On Hatch's left Gibbon advanced on the road to the gap, and when near it was checked, after a very stubborn fight, by Colquitt's brigade. It was dark when Hatch and Gibbon ceased fighting, both close up to the gap. On the right Meade's route lay over very broken ground, but crossing ravines, ascending steep hills and charging stone fences, he drove Rodes' brigade and its support from point to point, as it extended to the left, and finally turning it, swept to the left and reached the highest point of the mountain, commanding the summit of the gap, the road through it and the narrow open space around the Mountain House, on which Lee's defeated men were crowded in some disorder.

It was dark when this position had been gained and Hooker rested. He had lost 167 killed, 712 wounded and 44 missing. The total Union loss for the possession of Turner's Gap, including Fox's Gap, was 325 killed, 1,403 wounded and 85 missing; the Confederate loss, 248 killed, 1,013 wounded and 662 missing.

The result of the battle was that Lee abandoned his intended invasion of Pennsylvania and ordered an immediate retreat to Virginia. At 8 P. M. he ordered McLaws to abandon his position during the night and recross the Potomac near Shepherdstown Ford, leaving that ford for Longstreet's and Hill's commands, and about the same hour sent a dispatch to Jackson to march up the Virginia side of the Potomac to Shepherdstown Ford, to protect his crossing. These orders to McLaws and Jackson contemplated the abandonment of operations against Harper's Ferry. The trains, reserve artillery and reserve ammunition train, at Hagerstown, were ordered to cross the Potomac at Williamsport, and Toomb's brigade was ordered to march from Hagerstown to Sharpsburg. Between 10 and 11 P. M. Lee's army began its retreat from South Mountain by way of Boonsboro and Sharpsburg, D. H. Hill leading, with orders to cross the Potomac. While on the march Lee heard that Franklin had carried Crampton's Gap, thus shutting up McLaws in Pleasant Valley, upon which he ordered his column to halt at Keedysville to assist McLaws, who was now ordered to cross Elk Ridge, if possible, and join him at Keedysville or Sharpsburg, or to cross the Potomac at Weverton, below Harper's Ferry. Arriving at Keedysville, he could hear nothing of McLaws, and at daylight, 15 September, resumed his march for Sharpsburg, still hoping that McLaws could elude Franklin by crossing Elk Ridge. Before reaching Sharpsburg he heard that Harper's Ferry had fallen, and when across the Antietam he received a dispatch from Jackson stating that he would join him at Sharpsburg, upon which he concluded to give McClellan battle at that place, and immediately made dispositions to contest McClellan's passage of the Antietam, until Jackson, Walker, McLaws and Anderson could join him, by marching up the Virginia side of the Potomac. Consult 'Official Records' (Vols. XIX, LI); 'McClellan's Own Story'; Palfrey, 'The Antietam and Fredericksburg' (New York 1881); Allan, 'History of the Army of Northern Virginia in 1862' (New York 1867); The Century Company's 'Battles and Leaders of the Civil War' (Vol. II).

E. A. CARMAN.

SOUTH NORWALK. See NORWALK.

SOUTH OMAHA, Neb., formerly a city in Douglas County, on the Missouri River, and on the Chicago, Burlington and Quincy, the Chicago, Rock Island and Pacific, the Missouri Pacific, the Union Pacific and other railroads. It has steamer connection with many of the cities and towns on the Missouri, thus adding to its shipping facilities, especially the opportunities for cheap freight transportation. It was chartered as a city in 1885 and incorporated in the city of Omaha in 1915. Pop. about 27,000 at time of its incorporation with Omaha (q.v.).

SOUTH ORANGE, N. J., village in Essex County, on the Rahway River and on the Dela-

ware, Lackawanna and Western Railroad, five miles west of Newark and 15 miles west of New York. It was first settled in 1680 and was a part of the town of Newark until 1806, when the town of South Orange was separately incorporated. It is picturesquely situated among the Orange mountains and has many fine residences, being a favorite place of residence for New York business men. Though largely a residential village, it has manufactures of hats and gelatin. It contains a handsome town hall (completed 1895), a public library, a public high school and a Roman Catholic parish school. It is also the seat of two private schools for girls and of Seton Hall College (q.v.), a Roman Catholic institution. Pop. about 6,500.

SOUTH PASADENA, Cal., city in Los Angeles County, on the northeastern outskirts of Los Angeles, and on the Atchison, Topeka and Santa Fé Coast Line, the Salt Lake Route and the Southern Pacific railroads. The surrounding district is engaged in fruit raising and ostrich farming. Pop. 4,649.

SOUTH POLAR EXPLORATIONS. See POLAR RESEARCH.

SOUTH PORTLAND, Me., city in Cumberland County, on Fore River, opposite Portland, with which it is connected by four bridges and by ferry. It is a residential city and has a considerable business as a summer resort. Forts Preble and Williams are located here, each being garrisoned by two companies of coast artillery. The Maine School for Boys is situated here. Industries include boat building, flour mills, oil and lead works and railroad machine shops. Pop. 7,500.

SOUTH RIVER, N. J., borough in Middlesex County, on the South River, 25 miles southwest of New York, on the Raritan Railroad. There are extensive deposits of clay and molding sands in the vicinity and manufactures include bricks, fire-proofing materials, handkerchiefs, shirts and embroidery. Pop. 4,772.

SOUTH SAINT PAUL, Minn., city in Dakota County, on the west bank of the Mississippi River and on the southern outskirts of Saint Paul, on the Chicago, Great Western and the Chicago, Rock Island and Pacific railroads. It is an important livestock market, has extensive stockyards and a large packing industry. Manufactures include malt, plaster and cement, and there are tanneries, carshops and a foundry. Pop. 4,510.

SOUTH SEA. See PACIFIC OCEAN.

SOUTH SEA COMPANY, The, a joint-stock company, which, in consideration of certain exclusive privileges of trading to the South Seas, offered the English government easier terms for the advance or negotiation of loans than could be obtained from the general public. In 1720 the proposal of the company to take over the entire national debt (at this time about \$17,500,000) in consideration of receiving annually 5 per cent, was accepted and the company promised on return for this privilege (as it was regarded) a premium in their own stock of \$35,000,000. Professing to possess extensive sources of revenue the directors held out promises to the public of paying as much as 60 per cent on their shares. It became soon apparent that such magnificent promises could never be fulfilled and in a few months' time

the collapse came which ruined thousands. Several important cabinet officers were implicated in the fraud. About one-third of the original capital was saved, which was divided among the stockholders. Sir Robert Walpole was one of the chief opposers of the scheme. Consult Coxe, W., 'Memoirs of Sir Robert Walpole' (London 1802).

SOUTH SEAS. See PACIFIC OCEAN; POLYNESIA; MELANESIA; MICRONESIA.

SOUTH SHETLAND ISLANDS, Antarctic Ocean, a group of islands situated between lat. 61° and 63° 20' S., and between long. 54° and 63° W., off the north coast of Graham Land and 600 miles southeast of Cape Horn. The group consists of 12 larger and numerous smaller islands, which are rocky and mountainous. They were discovered by the Dutch navigator Dirk Gerrits in 1599. In 1908 they became a British possession. The seal fisheries are extensive.

SOUTH-WEST AFRICA PROTECTORATE, the territory known before the European War as German South-West Africa. Its official designation became "The Protectorate of South-West Africa in Military Occupation of the Union Forces," so named after its conquest by South African forces under General Botha on 15 July 1915. The territory was placed under the administration of the Union of South Africa by the Peace Treaty of May 1919. It includes the region lying between Angola (Portuguese West Africa) and Cape Colony and extending eastward to Bechuanaland. It is composed of Ovambo, Damaraland and Great Namaqualand; area, 322,450 square miles; pop. before the war, whites, 14,830, of whom 12,292 were Germans. The natives number about 250,000. The military force, including police, was 3,000 men. The region forms a rough triangular mass, with truncated apex resting on the Orange River and broadening northward; total length, 930 miles, and a mean breadth of 400 miles. Long regarded as an arid sandy waste, it was suddenly proclaimed a German possession in 1884 under the title of Lüderitzland. The claim was recognized—after some diplomatic negotiations—and the boundaries were fixed by two conventions with Great Britain in 1884 and 1890, and one with Portugal in 1886. The enclave of Walfish Bay (q.v.) had been annexed by England in 1878 and joined to Cape Colony in 1884. The only other harbors are Ogden, 180 miles off Cape Frio, Sandwich Haven, or Porto do Ilheo, and Angra Pequena Bay; in addition, the Germans constructed a new harbor at Swakopmund. The Namib Desert separates the sea from the inland districts, where farming is carried on. Water is scarce in the country, what rainfall there is being greatest in the north and east, diminishing toward the south and west, though boring is usually attended with good results. At Tsumeb and other places in the hinterland of Swakopmund copper mining is successfully carried on, while up and down the desert near Angra Pequena diamond mines are worked. The first diamond was discovered in 1908; since then \$37,000,000 worth of diamonds have been extracted. Neither gold nor coal has yet been found. Windhoek is the capital, via which a railroad connects Swakopmund and Angra Pequena, while another line runs from Wind-

hoek to Tsumeb. The total length of railways in operation in 1913 was 1,305 miles. The Deutsche Kolonial Gesellschaft für Südwest Afrika held a concession of the coast lands. (See WAR, EUROPEAN, COLONIAL CAMPAIGNS; BEYERS, CHRISTIAN FREDERICK). Consult Calvert, A. F., 'The German African Empire' (London 1916), and 'South-West Africa During the German Occupation' (London 1915); Frobenius, L., 'The Voice of Africa' (London 1913); Hassert, K., 'Deutschlands Kolonien' (Leipzig 1910); Johnston, Sir H., 'The Colonization of Africa' (Cambridge 1899); Keltie, J. S., 'The Partition of Africa' (London 1895); Koschitzky, M. V., 'Deutsche Kolonialgeschichte' (Berlin 1888); Lewin, E., 'The Germans and Africa' (London 1915); Schulze, L., 'Südwestafrika' (Berlin 1910); Zimmermann, A., 'Geschichte der Deutschen Kolonialpolitik' (Berlin 1914).

SOUTHAMPTON, south-ämp'ton or suth-hämp'ton, England, an important seaport town, county and Parliamentary borough in Hampshire, 71 miles southwest of London, on the innermost angle of the SOUTHAMPTON-WATER. Other streams almost surround the town, which occupies an acclivity and consists of two distinct parts. The walls of the older part, belonging to the Middle Ages, traverse the centre of the town and divide it from the modern portion. The gates of this ancient wall are quite remarkable; Bargate is embattled and machiolated and contains in its upper part the Guild Hall. Saint Michael's is an old Norman church with some fine stained glass and delicate traceries and a lofty tower. *Domus Dei* is an ancient hospital of the 12th century, whose chapel was for some time used by French Protestant refugees. The Royal Victoria Hospital is about six miles from the town at Netley near the ruins of a celebrated abbey. It was founded by Queen Victoria for soldiers of the foreign service, as well as those nearer home, at a cost of \$1,750,000. A medical school is attached to it, for the preparation of surgeons for the army medical staff; it is also headquarters for women army-nurses who are trained here for their profession. Other buildings are Holyrood and Saint Mary's churches, the town-hall, custom-house, Watts Memorial Hall, Philharmonic Hall, assembly-rooms, ordnance survey offices, baths, etc. Literary institutions include the free library and grammar school (1550); Trade School; Hartley College, founded for the advancement of the natural sciences, archæology, classical and Oriental literature and connected with the schools of Art and Science at South Kensington; Polytechnicum, Athenæum and theatres. The docks are extensive (250 acres) and the harbor one of the finest in the world. The Prince of Wales' dock is the largest single dock extant. There are carriage manufactories, machine works, breweries and distilleries, ship-building and a cattle market. The trade of the port is enormous. The imports are corn, meat, cheese, fruit, coffee, sugar, cattle, wool, hides and wood. The exports are cotton manufactures, leather, hats, hardware, books and clothes. There are fine parks in the town and Southampton Common, nearby, is a large tract which contains the race-track. Southampton was

founded by the Saxons and preserves much of its antique character. Pop. about 120,000.

SOUTHAMPTON, N. Y., village in Suffolk County, on the south shore of Long Island and on the Atlantic Ocean, 85 miles northeast of New York and on the Long Island Railroad. Its principal occupation is that of a summer resort. It has excellent fishing and bathing and many beautiful homes. There is a high school and the Rogers Memorial Library. Pop. 2,509.

SOUTHAMPTON INSURRECTION. See TURNER, NAT.

SOUTHARD, suth'ard, Samuel Lewis, American statesman: b. Baskingridge, N. J., 9 June 1787; d. Fredericksburg, Va., 26 June 1842. He was graduated from the College of New Jersey in 1804 and was afterward admitted to the bar of Virginia. In 1815 he was appointed associate justice of the Supreme Court of New Jersey in which capacity he served until 1821, when he was elected to the United States Senate. In 1823 he was made Secretary of the Navy and in 1829 held the same office in the cabinet of John Quincy Adams. He was appointed attorney-general of New Jersey in 1829 and was elected attorney-general of New Jersey and governor of that State in 1832. He was a member of the United States Senate, 1833-42. His publications include 'Reports of the Supreme Court of New Jersey, 1816-20' (1820); 'Centennial Address' (1832) and 'Discourse on William Wirt' (1834).

SOUTHBIDGE, Mass., town in Worcester County, on the Quinnebaugh River and on the East Thompson branch of the New York, New Haven and Hartford Railroad; about 71 miles southwest of Boston and 21 miles south by west of the city of Worcester. It was settled about 1730 by people from Medfield and included Sturbridge, Charlton and Dudley until 1801. It was incorporated as a poll-parish 28 Feb. 1801, as a town in 1816. The chief manufacturing establishments are optical works, shuttle works, woolen and cotton mills, knife works and printing works. The town is an industrial and commercial centre of great importance. The principal public buildings are the town-hall, public library, the Y. M. C. A. building, the churches and schools. There are seven churches, a high school, public and parish schools and a fine public library. The government is administered by annual town meetings. The French Canadian element predominates. Pop. 14,200.

SOUTHCOTT, Joanna, English fanatic: b. Gittisham, Devonshire, April 1750; d. London, 27 Dec. 1814. For many years she was in domestic service, attending the Established Church, but also going to Wesleyan meetings. In 1791 she joined the Methodists, but in 1792 left them and began to write prophecies in a combination of doggerel verse and incoherent prose. Converts followed the publication of her tract, 'The Strange Effects of Faith' (1801); the elect were to number 144,000 and their certificates for the millennium were drawn up. Joanna professed to interpret dreams and many absurdities and delusions attended her proceedings until her death by a brain disease. Her followers split into two minor sects, led respectively by John Ward and John Wroe. Consult Aikin (Pugh), 'Memoirs of Religious

Impostors' (1821); Mathias, 'The Case of Joanna Southcott.'

SOUTHCOTTIANS. See SOUTHCOTT, JOANNA; RELIGIOUS SECTS.

SOUTHDOWN, a breed of sheep (q.v.).

SOUTHEND, or **SOUTHEND-ON-SEA**, England, in Essex County, on the Thames, 42 miles east of London. The public buildings are the theatre, church and hall, technical schools and an isolation hospital. The marine park contains 26 acres, a revolving tower, pavilions, promenade piers and pleasure grounds. West-end is an attractive suburb, with many pretty villas. Southend is the chief station of the coast survey and is above all a much-frequented watering-place—the one nearest London. Its popularity began with a visit by Queen Caroline in 1804. The bathing is excellent. It has a fine pier and esplanade and a lighthouse. German warships bombarded Southend in 1915. Pop. about 60,000.

SOUTHERLAND, William Henry Hudson, American naval officer: b. New York, 10 July 1852. He was graduated at the United States Naval Academy in 1872. As a boy he served as a naval apprentice. He was commander of the *Eagle* in the Spanish-American War in 1898, serving on the Cuban coast. He was promoted through the various grades to the rank of rear-admiral 4 May 1910. He commanded the second division of the Pacific fleet in 1911-12; was commander-in-chief of the Pacific fleet in 1912-13; commanded an expeditionary landing force in Nicaragua in August-October 1912 and in 1913-14 he was a member of the General Board. He was retired upon reaching the age limit in 1914.

SOUTHERN BAPTIST THEOLOGICAL SEMINARY, located at Louisville, Ky. It was established by the Southern Baptists to provide an institution expressly for theological training and was opened in 1859 at Greenville, S. C. During the Civil War it was closed and reopened in 1865 under serious financial difficulties. In 1877 it was removed to Louisville, but the financial resources were precarious until 1880 when a large donation was received and the success of the institution assured. The course of instruction is divided into the following 10 schools: (1) Biblical introduction; (2) Old Testament interpretation; (3) New Testament interpretation; (4) systematic theology; (5) comparative religion and missions; (6) homiletics and elocution; (7) church history; (8) ethics and sociology; (9) pastoral theology; (10) Sunday school pedagogy. Of these schools, four have two departments; the school of Old Testament interpretation includes an English and a Hebrew department, the school of New Testament interpretation an English and a Greek department, the school of systematic theology a general course and a department of Biblical theology, the school of church history, junior and senior departments, the Hebrew, Greek, Biblical theology and senior church history courses are intended for students who have had a higher education, some preparation in Greek being necessary for the Greek course. There are also special courses for advanced work in each department. The degrees conferred: Th.G. (graduate in theology), Th.B. (bachelor in theology), Th.M. (master in the-

ology) and Th.D. (doctor in theology), the last for post-graduate work after the acquirement of the degree of Th.M. The buildings include New York Hall (a dormitory), Norton Hall, the Memorial Library Building and the gymnasium. The library in 1916 contained 25,000 volumes, the students numbered 341 and the faculty 11.

SOUTHERN BAPTISTS, the southern branch of the Baptist Church in the United States, which separated from the main body in May 1845 because of the difficulty of harmonizing the different sections on the slavery question. It is governed by the Southern Baptist Convention and has both Home and Foreign Mission boards, and Sunday school Boards, as well as many young people's societies. The Foreign Missions Board expends about \$300,000 annually, and has about 12,000 native members in Italy, Argentina, Brazil, Mexico, Africa, China and Japan. The Home Missions Board includes within its field Cuba and the insular possessions of the United States. It expends about \$200,000 annually. On 1 Jan. 1917 there were 23,692 church organizations; 2,711,591 members; and 15,946 ministers. The Sunday schools numbered 18,438, with 159,733 teachers and 1,656,324 pupils.

SOUTHERN BOUNDARY. See BOUNDARIES OF THE UNITED STATES.

SOUTHERN CALIFORNIA, University of, a co-educational institution for higher learning opened at Los Angeles in 1880. It has colleges of liberal arts, law, medicine, dentistry, theology, pharmacy, oratory, music and fine arts; and there is also a preparatory school and a Marine Biological Laboratory at Venice, on the Pacific Ocean, 16 miles distant. Its trustees are elected by the Southern California Conference of the Methodist Episcopal Church, but no religious qualifications are required of either students or faculty. The university is situated about three and one-half miles from the heart of Los Angeles. Its grounds and buildings are valued at \$600,000, and its library has 26,000 volumes. It had in 1918 4,427 students enrolled, 600 with the colors, and 313 instructors.

SOUTHERN COLLEGE, Birmingham, the chief educational institution of the Methodist Episcopal Church in the State of Alabama resulting from the union, in 1918, of the Southern University, situated at Greensboro, Ala., and Birmingham College, situated at Birmingham, Ala. Birmingham being the greater centre of population and possessing better transportation facilities, the whole college interests, except the high school at Greensboro, were centred in the former place. The Southern University was opened in 1859; but it had a difficult time during the Civil War and the reconstruction period. The State of Alabama was divided into two conferences of the Methodist Church in 1883; but both sections still continued to support the university. However, in 1896, the North Alabama Conference decided to establish a college for men. The new institution was opened in Birmingham in 1897, upon which the northern conference surrendered its interest in Southern University. On the union of Birmingham College and Southern University in 1918, the name

of Birmingham Southern College was adopted for the new institution. The college possesses a fine large administration building of brick containing a chapel, society halls, offices and recitation-rooms; three buildings for dormitories; a gymnasium; a residence for the president of the college, and a large modern science hall which houses the library, laboratories, storage vault and possesses numerous classrooms. The scheme of the Birmingham Southern College, as formed in 1918, contemplates ultimately erecting in all 23 buildings arranged according to a landscape scheme around a large campus on the highest elevation of the college grounds which consist of 63 acres, 40 of which are included in the campus. In addition to this Birmingham property the college also owns all the buildings and grounds of the defunct Southern University at Greensborough, together with the endowments belonging to the latter institution. Birmingham Southern College is administered by a board of trustees consisting of 24 members; and it has an annual endowment of \$20,000 from the two church conferences of the State; a productive endowment of \$75,000 and a second endowment of \$125,000. The college courses lead to two degrees, bachelor of arts and bachelor of science, and the M.A. degree is also conferred.

SOUTHERN CROSS, in astronomy, a constellation of the southern hemisphere, composed of four stars, one of which is of the first and two of the second magnitude. They form a figure not unlike a cross, especially when seen above the pole, and are the best-known of the southern constellations.

SOUTHERN MINNESOTA, University of, a co-educational institution giving normal and business courses, established at Austin by William W. Meiners in 1897. Its president in 1918 was W. W. Meiners, Ph.D., LL.D.

SOUTHERN PACIFIC COMPANY.
History.—The late Collis P. Huntington and his associates, who had built the Central Pacific Railroad, the Pacific end of the first trans-continental line, and the Southern Pacific Railroad lines in California, Arizona and New Mexico, and who had secured control of certain railways in Texas and Louisiana, extending from El Paso, Tex., to New Orleans, La., conceived the idea of forming the Southern Pacific Company in order to ensure perpetuity and harmony in the operation of the respective properties as parts of one through line. The Southern Pacific Company was created by a special act of the legislature of the State of Kentucky, approved 17 March 1884. Its charter, which was very broad, authorized it, among other things, to acquire, by purchase or otherwise, stocks, bonds or securities of any company, corporation or association, to construct, acquire, own, lease, maintain or operate railways, steamship lines, telegraph or any public or private improvements; and to buy, hold, sell and deal in all kinds of public and private stocks, bonds and securities. This was the first security-holding company organized to carry on extensive work. The organization of the company took place in August 1884, and active operations began on 1 March 1885 when the lease known as the "Omnibus Lease," went into effect. Under this lease, which included the

lines forming nearly all of the "Sunset Route" from San Francisco to New Orleans by rail and thence to New York by steamer, together with their lateral lines and branches, the Southern Pacific Company operated all the properties as one line, received all revenues and paid all expenses, including rents, taxes and interest, and divided the remaining profits, if any, between the parties to the lease on certain agreed percentages. This lease was terminated as to the lines in the State of Texas, in accordance with a statute of that State on 1 July 1889, and was terminated as to the remaining lines on 31 Dec. 1901. Since the termination of the Omnibus Lease the lines in Texas and Louisiana have been operated by their own organizations, but the Southern Pacific Company has continued to operate the Pacific system lines (which include Central Pacific Railroad, Oregon and California Railroad, Southern Pacific Railroad, Southern Pacific Coast Railway) under long-term leases. All of such lines, however, together with the ocean-steamship lines plying between New York, New Orleans, Galveston and Havana, have been dealt with as parts of the Southern Pacific "transportation system."

Following its incorporation the Southern Pacific Company proceeded to acquire the capital stocks of the companies owning the lines which formed its transportation system and on 31 Dec. 1917 owned all but \$81,700 of the \$349,082,400 of outstanding capital stocks of the companies mentioned in this article under *Mileage and Service*.

Mileage and Service.—The Southern Pacific system operates in the States of Louisiana, Texas, New Mexico, Arizona, California, Oregon, Nevada and Utah. Its transportation system, which extends from New York City, via New Orleans, La., and Galveston, Tex., to San Francisco, Cal., and Portland, Ore., with a line extending from San Francisco, Cal., to Ogden, Utah, was made up, as of 31 Dec. 1917, as follows:

	Miles of railway	Miles of water lines
Lines operated by Southern Pacific Company under long term leases:		
Central Pacific Railway.....	2,267	125
Oregon and California Railroad.....	1,214	
Southern Pacific Railroad.....	3,530	
Southern Pacific Coast Railway.....	107	
Lines operated by owning companies:		
Morgan's Louisiana and Texas Railroad and Steamship Company.....	401	
Louisiana Western Railroad.....	208	
Lake Charles and Northern Railroad.....	73	
Texas and New Orleans Railroad.....	468	
Galveston, Harrisburg and San Antonio Railway.....	1,361	
Houston, East and West Texas Railway.....	191	
Houston and Shreveport Railroad.....	41	
Houston and Texas Central Railroad.....	948	
Arizona Eastern Railroad.....	378	
Iberia and Vermilion Railroad.....	21	
Southern Pacific Company's Steamship Lines.....		4,400
Southern Pacific Terminal Company (Dock and wharf facilities at Galveston, Tex.).....		
	11,208	4,525
Less operated jointly by two or more companies.....	43	
Total.....	11,165	4,525

The service of the company includes routes as follows: (1) *Sunset Route*—between San Francisco and Los Angeles, Cal., El Paso, San Antonio and Houston, Tex., and New Orleans, La.; (2) *Atlantic and Gulf Steamship Lines*—between New Orleans and New York, Galveston and New York and New Orleans and Havana, Cuba; (3) *San Joaquin Valley Line*—between San Francisco and Los Angeles, Cal.; (4) *Coast Line*—between San Francisco and Los Angeles, Cal.; (5) *Ogden Route*—between San Francisco and Ogden, Utah; (6) *Shasta Route*—between San Francisco, Sacramento and Portland, Ore.

Operating and Other Income.—The following tabulation, showing the number of shareholders, the miles of road operated and the results of operation in 1917, the last year of operation before the property was taken over by the government under the Federal Control Act of 21 March 1918, compared with 1886, the first complete calendar year of operation, gives an idea of the company's growth:

	Year ended 31 Dec. 1917	Year ended 31 Dec. 1886	Per cent of increase
Number of shareholders of Southern Pacific Company	37,088	91	
Average miles of road operated	11,137	4,846	130
Freight revenue	\$132,608,207	\$18,668,421	610
Tons carried one mile	14,803,735,481	1,439,113,580	929
Freight-train miles	24,550,167	9,616,218	155
Passenger revenue	\$45,380,193	\$8,464,727	436
Passengers carried one mile	2,024,390,972	398,031,884	409
Passenger-train miles	31,085,797	5,953,054	422
Total operating revenues	\$193,971,490	\$31,797,882	510
Net revenue from miscellaneous operations, hire of equipment and rentals	8,080,390	284,797	2,737
Interest and dividends received and other income	7,248,979	544,535	1,231
Gross income	\$209,300,859	\$32,627,214	541
Operating expenses and uncollectible revenues	\$120,672,060	\$18,514,656	552
Railway tax accruals	13,792,176	888,623	1,452
Interest and other deductions	25,707,206	9,112,941	182
Total deductions	\$160,171,442	\$28,516,220	460
Net income	\$49,129,417	\$4,110,994	1,095
Per cent of net income on outstanding capital stock of Southern Pacific Company	17.65	3.27	439.76

In 1917 after appropriating \$978,097 for sinking funds and \$16,369,854 for dividends there remained a balance of \$31,781,466 which went to swell the surplus of the company.

Capital Stock and Funded Debt.—At 31 Dec. 1917 the capital stock and funded debt were as follows:

Capital Stock:		
Southern Pacific Company	\$272,823,405	
Proprietary Companies	349,082,400	
		\$621,905,805
Funded Debt:		
Southern Pacific Company	\$206,657,610	
Proprietary Companies	456,471,651	
		\$663,129,261

Of the proprietary companies' issues the Southern Pacific Company owns direct or through subsidiaries \$349,000,700 of capital stocks and \$97,689,590 of funded debt. In addition to these holdings \$11,471,000 of proprietary companies' bonds are held in sinking funds.

Assets and Liabilities.—The balance sheets of the Southern Pacific Company and its proprietary companies, translated into ordinary conversational language, show the magnitude of the company's property interests and financial strength: On 31 Dec. 1917 the combined obligations (debts) of every description, of the company and its proprietary companies, consisting of amounts owed to security holders, employees, tradesmen, connecting lines, tax collectors and others (not including \$51,874,598.08 of accrued depreciation on road, equipment and miscellaneous physical property) amounted to \$1,382,264,737.57. The companies held to meet such obligations assets (property) amounting to \$1,685,075,159.29 as follows: (1) Book value of the investment to transportation property carried on the books of the companies forming the Southern Pacific steam transportation system, consisting of 11,165 miles of first-main track, 561 miles of additional main track, 4,150 miles of yard track and sidings, 25 ocean steamships, 5 river steamships,

18 ferry-boats and car transfers, 10 tugs, 63 barges and 19 other vessels, the whole forming a transcontinental system extending from New York City, via New Orleans and Galveston to San Francisco, Cal., and Portland, Ore., with a line extending from Ogden, Utah, to San Francisco, Cal., \$983,482,275.20; (2) cash and interest-bearing securities in sinking funds for the redemption of outstanding funded debt, \$13,711,547.27; (3) investments in miscellaneous physical property consisting principally of (a) the California Fuel-Oil Department of Southern Pacific Company with an annual production of about 9,500,000 barrels of oil and annual gross earnings of approximately \$17,000,000, and (b) terminal and other real estate acquired in anticipation of future use, \$30,778,341.24; (4) investments in affiliated companies, \$523,560,538.04; (5) other investments, principally securities in outside companies, \$24,730,955.60; (6) current, deferred and unadjusted assets consisting of:

Cash	\$31,733,162 61	
Cash assets	27,319,549 20	
Material and supplies	24,406,115 91	
Deferred assets and unadjusted items	25,352,674 22	\$108,811,501 94
Grand total of assets		<u>\$1,685,075,159 29</u>

which exceeds all debts and obligations, including the outstanding capital stock, by an amount of \$302,810,421.72, of which \$51,874,598.08 represents reserves for accrued depreciation and \$250,935,823.64 represents an invested surplus which is equivalent to nearly 92 per cent of the outstanding capital stock. In addition the companies own 10,978,818 acres of unsold subsidy lands, allocated thus: (a) Central Pacific Railway Company, 7,076,215 acres; (b) Houston and Texas Central Railroad Company, 18,688 acres; (c) Southern Pacific Land Company, 3,883,915 acres; total, 10,978,818 acres; and have a claim against the United States for the value of 2,353,446 acres of unsold lands of the Oregon and California Railroad land grant taken over by the government under Act of Congress passed 9 June 1916.

Union Pacific and Southern Pacific Unmerger.—Following the death of the late C. P. Huntington the Union Pacific Railroad Company acquired a large block of Southern Pacific Company stock and this was augmented by later purchases until on 30 June 1912 the Union Pacific owned \$126,650,000 out of a total of \$272,672,406 of Southern Pacific Company stock. Suit was brought by the United States on the ground that the ownership of such stock by the Union Pacific Railroad Company was in violation of the Sherman Law and on 2 Dec. 1912 the United States Supreme Court held that the ownership of such stock by the Union Pacific Railroad Company was unlawful and ordered the sale of such stock.

General.—The Southern Pacific Company was one of the pioneers in the use of all-steel equipment, the first all-steel passenger car used on its lines having been placed in service in July 1906. Since that time it has constantly been adding to its steel equipment and for several years has followed the practice of purchasing only all-steel cars for passenger service and either all-steel or steel underframe cars for freight service. Of the 2,405 passenger-train cars in service at 31 Dec. 1917, 1,096, or 46 per cent, were all steel, and of the 51,187 freight-train cars in service at the same date 37,515, or 76 per cent, were either all steel or steel underframe.

To secure and maintain the highest standard of efficiency and safety of operation the Southern Pacific Company has for many years expended large sums in the substitution of steel cars for wooden cars; in the application of air-brakes, automatic couplers and other safety devices; in the elimination or adequate protection of grade crossings; and in the installation of automatic electric-block signals. As a result of such expenditures for safety devices, and of the unremitting efforts of the company's officers to maintain safe-working methods, the company transported 422,000,000 passengers in the 10 years ending 31 Dec. 1917 with but one fatality in a train accident.

SOUTHERN RAILWAY COMPANY.

The Southern Railway Company was chartered under the laws of Virginia, 1894, as successor to the Richmond and West Point Terminal Railway and Warehouse Company. It operates main lines in Virginia, North Carolina, South Carolina, Georgia, Tennessee, Alabama, Mississippi, Kentucky, Indiana and Illinois. There are also branches and spurs in these States, also in the District of Columbia. The lines owned extend 4,341.60 miles; those controlled through the ownership of securities, 1,456.68 miles, and the leased lines, 786.03 miles. The road covers, with its leased lines and trackage rights, practically all points of importance in the South Atlantic and Gulf States.

The Southern Railway, by its ownership of securities, controls the following leased lines: Southern Railway, Carolina division, 755 miles; Mobile and Birmingham Railroad, 150; Richmond and Mecklenburg Railway, 31; Georgia Midland Railroad, 98; Virginia and Southwestern Railway, 189; North Carolina Midland Railroad, 54; Elberton Southern Railway, 51. The lines controlled but not leased are: the State University Railway, 10 miles; Knoxville and Ohio Railroad, 69; Sievern and Knoxville Railroad, 17; Ensley Southern, 33; Cumberland Railway, 11; Tennessee and Carolina Southern Railway, 30; Roswell Railroad, 13. Other lines leased and trackage rights bring the aggregate length of line controlled by the Southern Railway Company, as above, to 7,102 miles.

Other Lines Acquired.—The Southern Railway Company also controls the Mobile and Ohio Railroad; Alabama Great Southern Railroad, 357 miles; Cincinnati, New Orleans and Texas Pacific Railroad, 336; Georgia Southern and Florida Railway, 391; Northern Alabama Railroad, 119. During the fiscal year ended 30 June 1917 the company acquired practically all the capital stock of the New Orleans and Northeastern Railroad, extending from New Orleans to Meridian, Miss., 195 miles.

The Alabama Great Southern Railroad is controlled by the Southern Railway Company through ownership of the majority of each class of its capital stock. The Southern Railway Company controls the Mobile and Ohio Railroad through ownership of more than 73 per cent of its capital stock and about 87 per cent of its general mortgage bonds. The Georgia Southern and Florida Railway Company is controlled through ownership of more than 58 per cent of its capital stock and the entire issue of its first consolidated mortgage bonds. The above companies are operated independently. Other lines in the same class are: Northern Alabama Railway; Atlantic and Yadkin Railway; Blue Ridge, Danville and Western Railroad; Tallulah Falls Railway; Lawrenceville Branch Railroad; Hartwell Railway; High Point, Randleman, Asheboro and Southern Railroad; Saint Johns River Terminal, and Yadkin Railroad.

The operating revenues in the year ended 31 Dec. 1917 amounted to \$90,716,569, earned by the transportation of 19,886,602 passengers and 37,063,095 tons of freight. The passenger travel averaged 55.99 miles at 2.183 cents per mile—aggregating in the year 1,113,473.875 passenger-miles and \$24,303,183. The freight traffic averaged 175.81 miles per ton, at a charge

of 0.897 cents per ton-mile—aggregating in the year, 6,516,208,527 ton-miles and \$58,450,029. The total operating expenses for the year amounted to \$60,113,508 and the total operating income was \$26,429,962, of which \$14,037,415 was net income. The appropriation for dividends was \$1,500,000 and for physical betterments, \$120,210. The surplus for the year was \$12,417,205.

The equipment of the road on 31 Dec. 1917 comprised 1,750 locomotives, 626 passenger coaches, 345 baggage, mail and express cars and 49,495 freight cars, of which 18,480 were coal cars.

The entire investment in the road and its equipment was \$416,468,542. Other investments of the company amounted to \$75,752,539. The total stock outstanding was \$180,000,000 and the long-term debt was \$253,275,500. The credit balance of the profit and loss account on the date quoted was \$43,288,162.

Descriptive.—The Southern Railway with its main artery extends from Washington, D. C., to Atlanta, Ga., where branches extend southward to Mobile, Ala.; eastward to Brunswick, Savannah and Charleston; westward to Chattanooga, Birmingham and Memphis; another westward branch also reaching Louisville and Saint Louis; while other ramifications extend to Harrisburg, Pa., Richmond, Va., and Norfolk, N. C.

SOUTHERNE, Thomas, English playwright and dramatist: b. in County Dublin, Ireland, about 1660; d. 26 May 1746. He was educated at Trinity College, Dublin, and entered the Middle Temple at London, but subsequently abandoned law to take up play-writing. His first play was 'The Loyal Brother, or The Persian Prince' (1682); this was followed by 'Isabella or the Fatal Marriage' (1694), which was afterward revised by Garrick; 'Oroonoko, or The Royal Slave' (1696), one of the earliest English condemnations of the slave trade; 'Sir Anthony Love, or The Rambling Lady.'

SOUTHERNWOOD, an ornamental and ordinary herb. See ARTEMISIA.

SOUTHEY, south'i or suth'i, Caroline Ann Bowles, English poetess, daughter of Capt. Charles Bowles, a retired officer, and second wife of Robert Southey (q.v.), to whom she was married in 1839: b. Lymington, Hampshire, 6 Dec. 1786; d. there, 20 July 1854. Owing to the death of her mother in 1816 and the loss of her property she was compelled to turn to literature for maintenance and in 1820 sent the manuscript of 'Allen Fitzarthur' to Robert Southey for approval. This led to considerable correspondence between them and finally resulted in their marriage in 1839. Meanwhile she had written 'Tales of the Factories' (1823) in verse; 'Solitary Hours' (1826) in verse and prose; 'Chapters on Churchyards' (1829), prose tales which gained her wide reputation; 'Selwyn in Search of a Daughter' (1835); 'The Birthday' (1836), etc. She also collaborated with Southey on the poem 'Robin Hood,' which was not, however, completed. After Southey's death she lived in retirement. Her collected poems were published in 1867. For bibliography see SOUTHEY, ROBERT.

SOUTHEY, Robert, English poet-laureate, historian, miscellaneous writer: b. Bristol, Eng-

land, 12 Aug. 1774; d. Keswick, England, 21 March 1843. His father was Robert Southey, a linen draper; his mother was Margaret Hill, daughter of Edward Hill, gentleman, of Westminster. Southey spent most of his boyhood in the care of his mother's half-sister, Miss Elizabeth Tyler of Bath. She gave him access to the theatre and to books, and, in his 14th year, sent him to Westminster School. There he remained four years; then, for publishing in the school paper a protest against excessive flogging, he was privately expelled. His mother's brother, the Rev. Herbert Hill, sent Southey to Oxford. He matriculated at Balliol College, 3 Nov. 1792. In his regular studies he was but little interested; but he read much and was especially influenced by the stoicism of Epictetus.

Southey's first important literary work, 'Joan of Arc,' an epic in 12 books, he composed during his summer vacation, 1793. He intended it as a tribute to the principles of the French Revolution; but the execution of the Girondins in October of that year cooled his enthusiasm. Then in June 1794 he found a new outlet for his ardor in the scheme of "pantisocracy" proposed to him by Samuel Taylor Coleridge. For lack of funds their plan for a colony on the banks of the Susquehanna ultimately failed. Southey was glad to accept an invitation from his uncle, the Rev. Herbert Hill, to visit Lisbon. The intended emigration, however, had one permanent effect: Southey had engaged himself to Edith Fricker; Coleridge, to her sister Sara. Before Southey sailed for Lisbon he married Edith, 14 Nov. 1795.

This marriage proved a great steadying influence on Southey's life. Returning from the Peninsula early in 1797, he made a serious attempt to study law, and, finding that he lacked ability in this, transferred his efforts to earning a livelihood with his pen. Within three years, besides much miscellaneous work, he published 'Minor Poems' (1797), completed 'Madoc' and planned 'Thalaba' and a 'History of Portugal.' In 1800 illness drove him again to Portugal, where he gathered material for his 'History' and completed 'Thalaba.' Recovered in health, he accepted a secretaryship to Isaac Corry, chancellor of the Irish exchequer, "a foolish office and a good salary" which he soon resigned. Back in England, he removed in 1803 from Bristol to Keswick. There Coleridge was established in "Greta Hall," and of this house Southey—to enable his wife to be near her sister, Sara Coleridge—took one-half. In 1809 he became owner of the entire house and harbored with his own the family that Coleridge had deserted.

Here was Southey's home for life. Here were born all but the first of his seven children. Here he brought together his library of 14,000 volumes. Here he did his work: kept in hand the epics from which he hoped for fame; gathered materials for that great history of Portugal destined never to be written; ground out the translations, histories, biographies and magazine articles, the glorified hack-work by which he met the growing needs of his own family and that of Coleridge. Pantisocracy, despite the pleadings of Coleridge, Southey had abandoned. But Southey had found a more practical idealism: he worked steadily and cheerfully; he met his business engagements punctually; he aided

younger literary aspirants with money and advice; and, although no longer as in youth a revolutionist, he championed in print more than one cause of progress and reform.

His work was not unrecognized. The *Quarterly Review*, to which, between 1808 and 1839, he contributed 95 articles, paid him during the latter part of that period £100 for each. In 1813 he was made poet-laureate. In 1820 Oxford conferred on him the degree of D.C.L. In 1826, without his knowledge, he was elected member of Parliament for Downton; and, when he protested that he lacked the proper qualification, Sir Robert Inglis promptly proposed that an estate of £300 a year be purchased for him. Southey, averse to public life, declined this offer, as he did that of Sir Robert Peel, in 1835, to make him a baronet. Peel, however, found means to be of use to Southey, for, by a general act for the recognition of distinguished services to literature and science, he obtained for Southey a pension of £300.

The last years of Southey's life were sad. On 2 Oct. 1834 he wrote: "I have been parted from my wife by something worse than death. Forty years she has been the life of my life; and I have left her this day in a lunatic asylum." In the spring they brought her back to Greta Hall. In the autumn she grew weaker. On 16 Nov. 1835 she "passed quietly 'from death unto life.'" Southey himself, still physically strong, was beginning to show mental weakness. In 1839 he married Caroline Bowles, the poetess, a friend of the Southneys for 20 years. Of his condition in 1840, Wordsworth wrote: "Southey did not recognize me till he was told. Then his eyes flashed for a moment with their former brightness, but he sank into the state in which I had found him, patting with both hands his books affectionately like a child." He died 21 March 1843.

Southey's literary work falls roughly into two groups: his poetry, for the most part early, before he was 30; his prose, for the most part later. The first group consists chiefly of long narrative poems: 'Joan of Arc' (1796); 'Thalaba' (1801); 'Madoc' (1805); 'The Curse of Kehama' (1810), and 'Roderick, the Last of the Goths' (1814). Legendary or mythological in subject, these poems embody in an exotic setting—Gothic, Arabian, Hindoo, what-not—their author's high-souled ethical ideals. For their setting and their philosophy these poems are worth reading but they are lacking in vital relation to life. Southey's stoicism made expression of lyric emotion unnatural; and he was too sincere to feign. Of the poems that he wrote as laureate—'Carmen Triumphale' (1814); 'The Poet's Pilgrimage to Waterloo' (1816); the 'Ephithalamium' and the 'Elegy for the Princess Charlotte' (1817); 'The Vision of Judgment' (1821), and 'A Tale of Paraguay' (1825)—the 'elegy' and the 'Tale' are the best. Southey's 'Poetical Works collected by himself' were published at London (10 vols., 1837-38).

His best work, however, was done in prose, notably in his 'Life of Nelson' (1813), and his 'Life of Wesley' (1820). His scholarly 'History of Brazil' (1810-19) is unfortunate in its subject. His 'History of the Peninsular War' (1823-32) is defective in its grasp of military movement and has been superseded by that of Sir William Napier. Of his translations of

mediaeval romances, the best is his 'Chronicle of the Cid' (1808). Chief among his other prose works are 'Omninia' (1812); 'The Doctor' (1834-37); 'Sir Thomas More, or Colloquies on the Progress and Prospects of Society' (1829); 'Life of Cowper' (1833-37), and 'Lives of the Admirals, or Naval History of England' (1833-40). And yet, among all his works, both prose and poetry, Southey will perhaps live longest by his nursery classic of 'The Three Bears' and by his verses 'After Blenheim.'

Southey was not a genius. He is not even to be classed with his friends, Wordsworth, Coleridge and Scott. Byron wrote truly when he said that Southey

"... had written much blank verse and blanker prose,
And more of both than anybody knows."

But Southey was at least a faithful workman and a worthy man. As even Byron admitted, he was for his time "the only existing entire man of letters."

Bibliography.—The best brief biography is that by Edward Dowden in the 'English Men of Letters' series (1879). Consult also Southey's letters, edited in six volumes by Rev. C. C. Southey (1849-50); in four volumes by Rev. J. Wood Varter (1856); and in the single volume edited by John Dennis (1887); Saintsbury, G. E. B., 'Southey' (in 'Cambridge History of English Literature,' Vol. II, New York 1914).

ARTHUR H. NASON,

Professor of English, New York University.

SOUTHINGTON, suth'ing-tôn, Conn., town in Hartford County, on the New York, New Haven and Hartford Railroad about 25 miles north of New Haven and 18 miles south by west of Hartford. It is on a small stream, Quinnipiac River, which furnishes considerable waterpower. The chief manufacturing establishments are hardware works including carriage supplies and drop forgings. Other establishments produce cutlery, ceiling and floor plates, tinmen's supplies, wood screws, shoe calks and rolling mill. In 1900 there were in Southington 65 manufacturing establishments, with a capital investment of \$2,783,709; the number of employees, 1,415; the wages paid annually, \$627,604; the cost of raw material, \$797,102, and the value of the product \$1,994,564. The educational institutions are the Lewis High School, the public elementary schools, "Lincoln School." There is a savings bank and one trust company; the combined capital of the banks is \$100,000. Pop. 6,516.

SOUTHPORT, England, in Lancashire, a fashionable seaside resort on the northwestern coast, about 18 miles by rail north of Liverpool. There is a fine beach as far as the latter town. The main street terminates in a public park, and the esplanade commands beautiful views of the Welsh Mountains. Attractive features are the Pavilion and Winter Gardens, which include an opera-house and concert-hall; marine drive and gardens; Cambridge Hall; Public Library and Art Gallery; Grecian town-hall; Victoria Baths, finest and largest in the kingdom; Victoria Schools of Art and Science, and hospital. There are numerous churches and about 200 schools; the museum stands in the fine botanic gardens. Pop. about 7,500.

SOUTHWARK (South'wark sometimes suth'erk), a metropolitan and parliamentary borough of central London, on the right bank of the Thames, and is, as its name implies, the south town. It came under the jurisdiction of the city in 1327. The choir and lady chapel of the Cathedral of Saint Saviour is the best example of early English architecture in London. The poets Gower, Fletcher and Massinger were interred in this church. The Roman Catholic Cathedral of Saint George is an imposing structure. The Metropolitan Tabernacle (associated with Charles Spurgeon) and Guy's Hospital are in the borough. Bankside Theatre, the scene of the first production of Shakespeare's plays, is on the river's bank. Marshalsea Prison is no longer in existence. John Harvard, the founder of Harvard College, was born in the Saint Saviour's district, but the house has been demolished. Pop. about 191,907. Consult Besant, 'South London' (1899); Boger, 'Bygone Southwark' (1895); Bower, 'Sketches of Southwark, Old and New' (1903); Manning and Bray, 'History of Surrey' (1804-05); Rendell, 'Old Southwark and Its People' (1878); Rendell and Norman, 'The Inns of Old Southwark' (1888); Thompson, 'Southwark Cathedral: Its History and Antiques' (1907).

SOUTHWELL, Robert, English poet and Catholic martyr: b. Horsham, Norfolk, about 1561; d. Tyburn, 21 Feb. 1595. He was educated at Douai and Paris under Jesuit influence and was ordained to the priesthood in 1584. In 1586 he returned to England, but owing to the penal laws against Catholics and especially against priests, was obliged to live in the greatest seclusion. In 1589 he became domestic chaplain to the Countess of Arundel and composed various pieces of prose intended to give comfort and encouragement to his co-religionists in their trials. Chief among the objects of his solicitude was the Earl of Arundel, under sentence of death in the Tower. On 20 June 1592 Southwell was arrested for visiting the house of Richard Bellamy, a Catholic under suspicion. He was many times tortured in order to extort from him confessions that might be used in prosecuting other Catholics; but his only answer was that he was a Jesuit and was prepared to die. In February 1595 he was tried for treason under the statute that prohibited the presence in England of Jesuits or seminary priests. He was hanged, drawn and quartered at Tyburn. Shortly after his execution collections of his poems were published and many subsequent editions have appeared. A collected edition was edited by Walter in 1817 and by Turnbull in 1856. Of his verse the most notable examples are 'Saint Peter's Complaint' and the 'Burning Babe,' a beautiful Christmas carol, of which there are different modern musical settings. Of his English prose tracts, 'Mary Magdalen's Teares' may be mentioned. His 'Complete Poems,' edited by Grosart are published in the 'Fuller Worthies Library' (London 1872).

SOUTHWEST TERRITORY, a territory of the United States, comprising all the region ceded by North Carolina (now Tennessee) and the narrow strip ceded by South Carolina. This was organized in 1790 as the Southwest Territory, with institutions resembling

those of the Northwest, except for the admission of slavery. With the admission of Tennessee, in 1796, and the organization of the Mississippi Territory, in 1798, the Southwest Territory went out of existence.

SOUTHWESTERN BOUNDARY. See BOUNDARIES OF THE UNITED STATES.

SOUTHWESTERN COLLEGE, a co-educational institution of higher learning established at Winfield, Kan., in 1886. It is under the control of the Methodist Episcopal Church and gives collegiate, academic, music, business, art and oratory courses. It grants the degree B.A. and is accredited by the State for the granting of teachers' certificates. In 1918 it had 300 students enrolled, 200 with the colors and 20 teachers.

SOUTHWESTERN LOUISIANA INDUSTRIAL INSTITUTE, coeducational institution at Lafayette, La., founded in 1898 by the State of Louisiana. Its first session began in September 1901. Six courses of study are given, as follows: The academic industrial course, teachers' course, teachers' course in agriculture and farm mechanics, teachers' course in home economics, one-year course in commercial accounting and a one-year course in stenography. A summer term of nine weeks is conducted by the Industrial Institute each year to enable its students in the teacher-training courses to continue their work from summer to summer while engaged in teaching during the regular session. The institute owns 50 acres of land, of which 25 are in use for the buildings and campus. It also rents about 100 additional acres for the needs of the demonstration farm. The buildings and equipment are valued at \$175,000. The attendance for 1915-16 was 372, and there were 29 instructors. Its income in 1915 amounted to \$107,749.83, of which \$88,750 was contributed by the State.

SOUTHWESTERN UNIVERSITY, located at Georgetown, Tex., established by the five Texas Conferences of the Methodist Episcopal Church, South. The movement for the establishment of the university was begun in 1869, the first session was opened in 1873 and the charter obtained in 1875. The charter rights of Ruterville College, Ruterville, McKenzie College, Clarksville, Wesleyan College, San Augustine and Soule University, Chappell Hill, were transferred to Southwestern University by order of the conferences and by special acts of the State legislature. Shortly after the establishment of the university, the need of college education for women in the South led to a movement which resulted in the organization of the Ladies' Annex. Originally the Annex was under the charge of the same faculty, but all classes were separate; exception was made in the case of scientific laboratory work. In 1900 the Annex was more closely affiliated with the university, and the women students of the Annex admitted to all college classes with men. The degrees conferred are B.A., B.S., B. Music, M.A., and M.S. The School of Fine Arts offers instruction in art, elocution and music. The campus is in three tracts, the Fitting School campus, the Annex campus and the College campus. Giddings Hall, a dormitory for men and five residence cottages are near the Fitting School; a new college building

was completed in 1900 for scientific laboratories and the library. The students in 1918 numbered 877, the instruction staff, 34. A library of 30,000 volumes is maintained.

SOUTHWORTH, Emma Dorothy Eliza Nevitte, American novelist: b. Washington, D. C., 26 Dec. 1819; d. there, 30 June 1899. In 1840 she was married to Frederick H. Southworth of Utica, N. Y., was thrown upon her own resources two years later and engaged in teaching in Washington in 1844-49. Her first story, 'The Irish Refugee,' appeared in the Baltimore *Saturday Visitor*, and she subsequently wrote for the *National Era* and the *New York Ledger*. Her work is characterized by some dramatic power and is still popular with uncritical readers, having been republished abroad and translated into several languages. She was a prolific writer and more than 60 novels were originally issued serially. A uniform edition of her works beginning with 'Retribution,' including 'The Hidden Hand,' which was successfully dramatized, and ending with 'The Fatal Secret,' was published in 42 volumes in 1872. Among her later works are 'Unknown' (1874); 'Mother's Secret' (1883); 'An Exile's Bride' (1887).

SOUTHWORTH, Franklin Chester, American Unitarian clergyman: b. North Collins, N. Y., 15 Oct. 1863. He was graduated from Harvard in 1887 and from the Harvard Divinity School in 1892. From 1887 to 1889 he taught Latin and Greek at Fish's School for Boys in Worcester and at the Adams Academy, in Quincy, Mass. Entering the university he was pastor of the First Unitarian Church, Duluth, Minn., 1892-97, and of the Third Unitarian Church of Chicago, 1897-99. In 1899 he became secretary of the Western Unitarian Conference, an organization composed of all the Unitarian churches in the Central West, among which he traveled extensively for three years, preaching, lecturing and attending conferences. In 1902 he became president of the Meadville Theological School and professor of practical theology, which position he still holds. In 1909 he gave a series of lectures in Manchester College, Oxford, England, and gave a number of sermons and addresses at London, Liverpool, Manchester and other English cities. He has three degrees from Harvard, was awarded the degree of doctor of divinity by Buchtel College in 1911 and the degree of doctor of laws by Allegheny College in 1915.

SOUEVRE, soo-vèstr, Emile, French novelist and dramatist: b. Morlaix, 15 April 1806; d. Paris, 5 July 1854. His literary work was an issue aside from the business of his life, and he was successively clerk, schoolmaster, journalist and in 1848 professor of administrative style in a civil service school. His 'Un philosophe sous les toits' was crowned by the academy in 1851 and in the August following his death his widow received the Lambert prize founded in honor of the memory of the writer who had conferred the highest service. He was the author of 'Derniers Bretons' (1835-37), and 'Foyer Breton' (1844), works embodying the folk-lore and natural features of his native province; also 'Pierre et Jean' (1842); 'Confession d'un ouvrier' (1851) and other fictions; besides dramas, works of travel and biographies. His principal contribution

to literature consists in the vivid pictures he has given of the life and manners of the Bretons.

SOVEREIGN. (1) *In politics* the highest person in a State; applied also adjectively to the highest power in a State, or to a State which exercises supreme or independent authority. Thus the legislature in its various branches is the sovereign power in each State, though the name of sovereign in a limited monarchy is reserved for the monarch, and a State which owns no superior is termed a sovereign State. (2) a gold coin, the standard of the English coinage. It exchanges for 20 shillings sterling, or about \$5.

SOVEREIGNTY, *in political science* the supreme power in a State by which the government is administered. In republics generally it is held that sovereignty resides in the people, but in some countries, like Japan, it is held that it is possessed by the sovereign. Various theories have been advanced as to the origin of sovereignty, some contending that it is the prerogative of the stronger force, others that it is created by divine sanction and still others that it is created by voluntary contract or that it is a property right descending in regular line of succession. Milton and Locke in the 17th century contended that the people were the ultimate source of political authority and the same principle was advanced by the French Revolution. The Declaration of Independence asserted the same doctrine when it declared that "governments derive their just powers from the consent of the governed," and in political addresses of the time the principle was frequently enunciated in all sections of the country that the people had the right to alter their governments whenever and in whatsoever manner they deemed expedient. These principles were embodied in the State constitutions, and even the right of revolution was therein asserted. The doctrine of popular sovereignty is almost universally accepted in Europe at the present time.

Sovereignty is of two kinds: internal and external. Internal sovereignty includes all governmental powers which a State possesses over its own citizens or foreigners domiciled therein and over private ships on the high seas. External sovereignty includes the right to enter into relations with foreign states, as by treaty or by declaring war.

There has been much contention as to whether each State in the Union is vested with sovereignty or whether it resides solely in the United States. The prevailing view is that the sovereignty of a State is legally limited and, therefore, not absolute, although before the Civil War this view was not at all general.

Internal sovereignty is divided into political sovereignty and legal sovereignty. Political sovereignty is the final supreme power residing in any political society. Legal sovereignty is the power which is in legal control at any specified period. Other distinctions are *de facto* and *de jure* sovereignty, the former of which is sovereignty that has been assumed but is obeyed by the citizens, though not resting on a legal basis, and the latter of which is sovereignty founded on law. Some authors refuse to recognize these two distinctions.

A State may have internal sovereignty but

not external sovereignty, as by yielding its right to make war or to negotiate with other States. In international law, however, such States, while subject to other States, are treated as sovereign powers. Under this head are included protectorates and suzerainties.

Some recent writers advocate the elimination of the term sovereignty from political science on the ground that it is synonymous with absolutism and should not be applied to the supreme power in any constitutional, Federal or similar government.

SOVIET (pron. sävyet'), a Russian word signifying council, advice, harmony, concord; *sovietnik*=councillor. Under the old régime the Tsar's Council of Ministers was called the "Soviet of Ministers," but the term has been invested with a new meaning since the Russian Revolution of March 1917. The popular organizations which then came into existence were called "Councils of Workmen's and Soldiers' Deputies," bodies which were supposed to be holding things together under the provisional Government until the election of the Constituent Assembly could take place; in a sense, they were vigilance committees designed to guard against counter-revolution. The Petrograd Soviet of 4,000 members was the most important of these, on account of its position in the capital and its influence over the garrison. By degrees the orderly and moderate element was pushed out of this group and the extremists who demanded "all power to the soviets" became supreme. When the Constituent Assembly eventually met, the Bolsheviks and their allies were in a minority, yet they succeeded in breaking up the Assembly and finally came out with their own program, the so-called "soviet government." Chaos and disorders paralyzed the upholders of constitutional democracy because they lacked both authority and the power to restrain the wild elements. The latter, on the other hand, possessed the Red Guard, a powerful armed mob, while the Soviet leaders—mainly ambitious doctrinaires—saw in the instrument of their creation a road to fame and power. Soon the Soviet system was invested with intellectual justification as "a higher type of State" and "a higher form of democracy" which would "arouse the masses of the exploited toilers to the task of making new history." Furthermore, it offered "to the oppressed toiling masses the opportunity to participate actively in the free construction of a new society." According to Lenine, the author of these quotations, Soviet rule "is nothing else than the organized form of the dictatorship of the proletariat." A loose code of rules governing elections to the soviets was framed, but the following classes were disqualified to vote: "Those who employ others for profit; those who live on incomes not derived from their own work—interest on capital, industrial enterprises or landed property; private business men, agents, middlemen; monks and priests of all denominations; ex-employees of the old police services and members of the Romanoff dynasty; lunatics and criminals." With village and factory soviets as a base, there arises a vast pyramid of district, cantonal, county and regional soviets, each with its executive soviet. Over and above these stands the "All-Russia Soviet Congress," which appoints an All-Russian

Central Executive Committee of not more than 200 members, which in turn chooses the Soviet of People's Commissaries—the Ministry. Beginning with a minimum of three and maximum of 50 members for smaller communities, the maximum for town soviets was fixed at 1,000 members. According to its founders, this system is destined in the future to replace all other forms of government in the world.

For good or ill, a new system of government has appeared in Sovietism. Not a little speculation has been aroused in countries outside of Russia and a considerable number of political thinkers have analyzed the future possibilities of Soviet rule. The reign of terror and bloodshed, which accompanied that rule in Russia may be regarded as an accidental transitory phase in the history of a country where violent occurrences are no novelties. It is necessary to separate barbarity and invidious class distinctions from Sovietism itself and to consider the latter purely as a political experiment of some importance. The essence of the conflict between the Parliamentary and the Soviet systems is whether the basis of representation shall be political or economic, using these words in their narrowest sense. The conception of the Soviet as ultimately representative of the local economic groupings—factories and productive areas—explains the enthusiasm of the neo-Marxians (who admit no politics outside the economic sphere) for the Soviet system, the elements of which they see in the works committees and such like combinations in modern large-scale industry. Some admirers, however, regard the Soviet system as a dual one with parallel political and industrial organizations, though it is probable that in practice the two branches merge in a single channel, the economic. Here we have only to ask whether a factory's political Soviet would be likely to work independently of its economic Soviet to realize that a separate standpoint is possible only in theory. The Soviet government in Russia claims to be in such close relations with the proletarian organizations on which it is based that "at all times the greater part of the population joins in the administration of the state" and that every worker may initiate in his Soviet a plan for reorganizing his industry which has only to be examined by the Soviets higher up and ratified to become law! If the Soviet system really fulfilled its claim to instruct the elector by giving him actual administrative experience, this would be a good argument in its favor, but in practice the demagogue and the party man dominate the high Soviets and these in their turn lord it over the lesser bodies. Hence the value of the system as an administrative training school disappears and the machine offers nothing useful that could not be obtained by Parliamentary government. Many sincere democratically-minded people in other countries have grown dissatisfied with their systems of Parliamentary government and have consequently been half prepared to welcome the Soviet idea as an alternative. Various causes have been advanced as being responsible for diminishing the prestige of Parliaments, such as their remoteness from public opinion, which elects but cannot recall them; the congestion of legislative business and the difficulty of carrying out necessary reforms;

the party system and the caucus; the corruption arising from personal and corporate pressure and the encroachments of cabinets. The Soviet system professes to remove these defects and also to introduce reforms which seem unattainable under Parliamentary government one of the chief being the creation of small and compact local administrative units to replace the existing large and unwieldy geographical electoral units. Many theorists, indeed, regard the Soviet system not as necessarily an instrument of proletarian dictatorship, but rather as a federation of local electoral groups, which, guided by intelligence and with toleration, could be transformed into a genuinely democratic form of government. Others, again, vision a possibility of separating the political and industrial spheres, while extending to both the means of self-government. In comparing existing institutions with visionary alternatives the advocates of the latter not infrequently fail to foresee the many defects which are not immediately apparent, but must inevitably be expected to arise. In no country have both these systems been fully tried, for Russia has never had real Parliamentary government, and in Bavaria, where a Soviet republic was established in February 1919, the venture so far has not presented the unassailable argument of success. It is difficult to see that the Soviet system can claim any tangible advantage over its rival, especially as the apex of the Soviet pyramid is far more remote from the individual elector than any Parliament or Congress. Altogether it seems easier and safer to overhaul and improve the solid machinery of a stable government than to cast it aside in favor of an abstract conception of doubtful value.

HENRI F. KLEIN,

Editorial Staff of The Americana.

SOW-THISTLE, a genus (*Sonchus*) of herbs of the order *Compositæ*. The species, of which there are about 30, are natives of the Old World, but some have become widely naturalized in temperate climates. They have alternate leaves, blue or yellow flowers in heads and beaked seeds crowned by fine white down. The common sow-thistle (*S. oleraceus*) is an annual which grows about 30 inches tall, has yellow flowers, and is found usually in rich soils. Its young leaves and tender tops are used as a substitute for spinach in northern Europe. The alpine sow-thistle (*S. or Lactuca, alpina*) is a native of mountainous Europe. It has beautiful blue flowerheads. The beach sow-thistle (*S. maritimus*) grows in saline soils in southern Europe, and is specially attractive because of its yellow flower-heads. These species are sometimes cultivated in gardens.

SOWER, or **SAUR**, Christopher, German-American printer: b. Laasphe, near Marburg, Germany, 1693; d. Germantown, Pa., 25 Sept. 1758. After a study of medicine at Halle, he came to Philadelphia in 1724, was for a time a farmer in Lancaster County, but in 1731 removed to Germantown, where he acted as an importer of German Bibles and religious works. In 1738 he obtained a printing-press and began the publication in German of a 24-page almanac, which continued to appear until 1798. He began in 1739 *Der Hoch-Deutsch Pennsylvanische Geschichtschreiber*, a religious and secular magazine, the first periodical in German in the

United States. It was published at first quarterly at three shillings per annum and afterward monthly. He established (1738) the first type-foundry in America, made his own ink for printing and later manufactured his paper and did his binding. In 1743 he published, in German, a Bible of small quarto size, Luther's translation, the edition being limited to 1,200 copies of 1,284 pages. With the exception of Eliot's Indian Bible, this was the first Bible printed in the colonies and it was the largest work that had then been attempted. An English Bible was not printed until 1781 by Robert Aitken at Philadelphia. Sower may have invented cast-iron stoves; he introduced them into general use. Consult Thomas, 'History of Printing in America' (1870); Ringwalt, 'Encyclopædia of Printing' (1871).

SOY BEAN, a leguminous plant (*Glycine hispida*), sometimes incorrectly called soja bean, native to southeastern Asia. It has been cultivated from ancient times and in some countries, notably Japan, it forms an important article of food. It was introduced into England in 1790 and into America some years later, where it was first grown principally in the southern States. Its use as a food for man has not become general except in its original home in Asia, and it is only within recent years that its value as a feed for stock has brought it to the attention of the western countries. The soy bean is an annual, two to four feet high. It has branching, hairy stems with trifoliate, hairy leaves. The flowers are inconspicuous, of pale lilac or violet color, and the fruit is a broad, two- to five-seeded pod, covered, like the rest of the plant, with stiff, reddish hairs. The seeds vary in color according to variety. When grown for the seed the crop sometimes yields as high as 40 bushels or more to the acre, but the average is much less. As a forage crop it makes as high as two to three tons of cured hay per acre. The fact that the flowers are self-pollinated gives it an advantage over many other legumes in introducing it into new regions. (See *DOLICHOS*). Innumerable varieties and forms of the soy bean have been developed in the original home of the plant. Several different varieties have been introduced into the United States, these being distinguished largely according to the shape, size and color of the seed, in the degree of hairiness and in the time required for the plants to reach maturity. The early varieties are preferred when the plant is grown for seed, while the latter give better results as forage crops. Some of the advantages claimed for it as a crop are that it is able to gather the food of sustenance in relatively poor land and by its power to assimilate nitrogen from the air to enrich the soil in which it grows. It is relatively sure of producing a crop of seeds very nutritious to livestock, for which it is adapted to use in various forms.

Soy beans require about the same conditions for growth as corn, but have somewhat better powers of resisting drought. The seed is not planted until the ground is thoroughly warm in the spring, and the earlier varieties are grown with fair results by planting after an early grain crop has been harvested. When planted for forage the seed is often sown broadcast, but where a crop of beans is desired it is better to plant in drills. The stage of growth at

which to harvest depends upon the use to be made of the crop. In the United States the soy bean is grown exclusively as a feed for stock, in pasture, as a soiling crop, for hay, or as a green manuring crop. The green feed and hay are excellent for cows in milk. The beans are usually fed in the form of meal and owing to the richness in protein and fats have been found of peculiar value in compounding feed rations. Fed in connection with less concentrated feeds and grains having a lower protein content, results have been obtained that show the soy beans to compare favorably in feeding value with cottonseed meal. The peanut is the only raw vegetable that contains as high a percentage of digestible protein and fat.

The soy bean is prepared for use as human food in a variety of ways in Japan, where it furnishes the protein that is lacking in a diet of rice. The plant is also grown in Europe and used there to a limited extent as human food. Since the beans contain no starch they are sometimes recommended as food for persons suffering from diabetes; a soy-bean bread has been manufactured for this purpose. Under the name of coffee bean, the soy beans have been placed on the market in America as a substitute for coffee.

In the United States the soy bean is best adapted to the southern and central States. It is not adapted to the States along the northern border or to the States west of the Rocky Mountains. In those States where it thrives it is especially valuable to soils that have become depleted of their nitrogen. The chemical composition of both bean and fodder adapts it especially to use as a balance ration in connection with corn and makes its cultivation desirable where no other protein feed is available. Consult 'Farmer's Bulletin' (Nos. 58, 372, 509, United States Department of Agriculture, Washington 1897-1914).

SOYER, swā-yā, **Alexis Benoit**, French cook: b. Meaux-en-Brie, 1809; d. England, 5 Aug. 1858. Leaving Paris in 1830, he served the Duke of Cambridge and became the chef of the Reform Club, 1837-50. In 1847 he received an appointment from the government to go to Ireland, which was then suffering from famine, and there he built several kitchens and served food at about half the ordinary cost. In 1855 he went to the Crimea, reorganized the victualing of the hospitals, improved the food of the army and navy and introduced cooking wagons. He was the most famous cook of his time and is immortalized as the Mirolofant of Thackeray's 'Pendennis.' His writings on cookery were widely read and include 'Culinary Relaxations' (1845); 'Charitable Cookery' (1847); 'History of Food in all Ages' (1853); 'The Shilling Cookery Book' (1854). Consult Volant and Warren, 'Memoirs of Alexis Soyer' (London 1858).

SOYESHIMA, Tanéomi, Japanese statesman: b. Saga, Province of Hizen. At Nagasaki in 1866 he studied under Guido F. Verbeck, an American missionary, giving especial attention to the United States Constitution and the New Testament. In 1868 he became a commissioner for formulating laws and subsequently an imperial councillor. In 1871 he was sent to Siberia to adjust boundary questions relating to the island of Sakhalin. Returning to Japan

he resigned his place in the Cabinet, but was later asked to return to it. On a visit to China in 1876 he was received with high honors by the mandarins by reason of his scholarship and he became private adviser of the emperor.

SPA, spä or spâ, Belgium, in the province of Liège, 20 miles southeast of the town of that name, a fashionable watering place, picturesquely situated, in an undulating country covered by woods and containing wonderful medicinal springs. There are delightful promenades in the environs. The casino, bath-house, public squares and hotels are interesting features, besides a new parish church and the Gallery Leopold II, with its museum, music-halls, reading-rooms, etc. Gambling was prohibited in 1902. The town is renowned for its lacquer ware. There are tanneries, forges and foundries. Spa was early famous as a resort and frequented by Russian and Swedish potentates and all the fashionable world. The generic term for mineral baths was thus derived. The waters are exported to the most distant countries and are efficacious in nervous diseases, anæmic troubles, dyspepsia and general debility. In 1918 the German general headquarters was located at Spa. Here took place the consultations of the general staff preceding the signature of the armistice and from here went forth the delegates appointed to meet Marshal Foch to sue for peace. Pop. 8,357. See WAR, EUROPEAN.

SPACE, that phase of the world which we express in terms of right and left, forward and backward, up and down, etc.; the actual experienced system which we are accustomed to handle by means of geometry. Many theories have been held concerning its nature. The ancient views are not at all clear, but until Aristotle, at any rate, the existence of empty space is not recognized and there is a general tendency to subordinate space to matter. The modern theory of space begins with Descartes, who makes extension the distinguishing mark of matter. Spinoza, though he finds in matter an attribute of God rather than an independent substance, follows Descartes in this respect. Leibnitz does not attribute to space an independent existence, but makes it merely an unclear recognition of the logical relations of the monads. Newton on the other hand, claims an independent existence for space and maintains that position is absolute, not relative. Kant solves the dispute between Leibnitz and Newton by finding in space and time, respectively, that a priori form of the external and internal senses, so that geometry is independent of experience, yet spatial entities do not exist apart from sense. Among the present views on the subject is the curious one of Bergson, who regards the spatial description of the universe as a scientific, intellectual perversion of the temporal flux is directly presented to intuition.

The old dispute as to whether the idea of space is innate or acquired belongs to a past stage of philosophical discussion and one may take it as an established fact that the empirical status of extension is quite analogous to that of any of the sensory qualities. Just as my experience of this red blotter before me is preconditioned by the fact that I am so constituted — unlike some color-blind persons — as

to be able to perceive red, so my experience of space depends on my having a nature fitted to perceive spatial entities. Indeed, it seems that as far as the mere nature of the experience is concerned, there is no reason for dividing qualities into the primary, such as those of space and time and the secondary, of color, sound, etc. The distinguishing characteristics of space reside in its organization rather than in its quality. This organization forms the subject matter of geometry, it is probably dependent in part on the intrinsic nature of the things which are in space and go to make up our spatial experience, but it is unquestionably also in a large measure dependent on the arrangement which we more or less consciously make of these sense-data, and by the arrangement of the entities of any system a system may be obtained whose formal properties are just about what you choose. Space thus becomes, as Poincaré has shown, a more or less pliable tool for scientific description, so that the question, "What is the structure of space?" may almost be translated into "What spatial structure is the simplest and most manageable for purposes of scientific description?" As a consequence, as the formulæ of science do not seem to be markedly simplified by the postulation of a non-Euclidean space (see GEOMETRY, NON-EUCLIDEAN) or of any other spatial structure other than that which is familiar to us in our elementary geometry and as this elementary geometry is simpler in its formulæ than non-Euclidean geometry or other similar systems, we choose — albeit unconsciously — the structure of our space in such a way that it shall be Euclidean. The three-dimensional character of space is likewise due to the fact that a three-dimensional system forms the simplest and most appropriate background to the observed facts of physics and is not, as Kant supposed, an *a priori* truth. If we should suddenly find masses varying in such a manner as to be susceptible of an easy and direct explanation by a motion perpendicular to our space, the very next work on physics would speak just as confidently of a space of four dimensions as we now speak of a space of three. A change of a similar nature has taken place in the last few years. (See RELATIVITY, THE PRINCIPLE OF). Whereas space and time were formerly conceived as completely independent dimensions, the present attitude of physics is that a body in unaccelerated motion carries with it, as it were, a space which is essentially distinct from the space with reference to which it is in motion and that distances are not the same when measured with reference to two sets of axes in relative motion. In other words, the system of reference of modern physics cannot be divided into independent spatial and temporal parts, but constitutes an essentially homogeneous spatial-temporal manifold, which is a Euclidean four-dimensional space with real minimal lines. See ANALYTICAL METRICS.

The problems of the infinitude and the infinite divisibility of space and of unoccupied space are again matters of scientific convenience. It is far simpler for the scientist to have a system of reference which does not depend on the entities which are referred to this system than to be continually hemmed in by the limitations of matter and the construction of a

system without lacunæ from a system which possesses them is no very difficult logical task. Consequently, the space of science is physically independent of its occupation by matter.

The problem of the extension of the world forms the subject matter of one of Kant's antinomies; that of its infinite divisibility is the subject matter of another. Both of these antinomies or paradoxes have a double aspect. Mathematically, they involve the motions of infinite collections and dense series, which have only received a satisfactory logical treatment within the last half-century. The infinitude of space and its infinite divisibility are again merely the results of the scientist's protest against the complications brought into his work by the supposition of a limited space or a space which offers obstacles to repeated division. Thus Kant is both right and wrong when he solves these antinomies by making space and time forms of perceptive experience, not things in themselves. He is right in so far as the infinitude and infinite divisibility of space emanates from ourselves and not from the object, but wrong in that he believes that infinitude and infinite divisibility involve unavoidable contradictions. (See ASSEMBLAGES, GENERAL THEORY OF; KANT). Consult Bergson, Henri, 'Time and Free Will' (trans. by F. L. Pogson, New York 1910); Deichmann, 'Das Problem des Raumes in der griechischen Philosophie bis Aristoteles' (Leipzig 1893); Mach, 'Space and Geometry in the Light of Physiological, Psychological and Physical Inquiry' (trans. by J. McCormack, Chicago 1906); Poincaré, Henri, 'The Foundations of Science' (trans., New York 1913); Robb, A. A., 'Theory of Time and Space' (Cambridge 1914); Russell, B. A. W., 'Essay on the Foundations of Geometry' (Cambridge 1897).

SPACE OF DIMENSIONS. See HYPER-SPACES.

SPADA, spá'dä, Leonello, or **ESPAÑA**, Italian painter: b. Bologna, 1576; d. Parma, 1622. He became the pupil of Carrachos and César Baglioni and an intimate friend and imitator of Caravaggio whom he considered his master and with whom he traveled. On his master's death he returned to Bologna and spent his latter days at the court of the Duke of Parma. Espada's power developed, when freed from the direct influence of Caravaggio removed by the death of the latter. He developed a style until then unknown in painting, in which he showed a surprising mastery of color and of *claro-obscuro* and displayed creative talent uncommon even in his day. Among his works (which are well known in European galleries) are 'Santo Domingo,' represented as burning the heretical books (Santo Domingo Church Bosco); 'San Jerónimo' (in the same church); 'Abigail giving provisions to David for the Army' (in the church of the Madonna della Ghiara, in Reggio); 'Judith'; 'Esther'; 'The Madonna Crowned'; 'The Aurora' (frescoes and paintings in the same church). In Parma, where Espada was court painter to the duke, he decorated the theatre of the capital in such a fine style that there was none other equal to it in his day, and he left the mark of his genius everywhere throughout the city in the shape of talented paintings, among them being 'The Virgin and Saints' (in Santo Sepulcro);

'San Félix' (in Capuchinos); 'Christ' (in Steccata); 'Piedad' (in Santa Cataline College); 'Christ before Pilate'; 'Saint Peter Denying his Master'; 'Death of John the Baptist'; 'Judith' (in the city art galleries). Espada's paintings are scattered throughout most of the larger cities of Italy and many of them have found their way outside the country. Among the best known of those not already mentioned are 'The Virgin and San Francisco de Asisi' (in Modena Gallery); 'Auto-retroto of Espada' (in Florence gallery); 'Christ tied to a Pillar' (in the Naples Museum); 'The Chastity of José' (Faragina gallery, Genoa); 'Jesus Crowned with Thorns'; 'David with the Head of Goliath'; 'Cupid Playing with a Leopard' (all in the Dresden Museum); 'Return of the Prodigal Son'; 'Death of San Cristóbal' (in the Louvre); 'Santa Cecilia' (Madrid Museum).

SPADE-FOOT TOAD, a toad (*Scaphiopus holbrookii*), resembling the common toad in general appearance but differing from it so greatly in structure as to be placed in a distinct family (*Scaphiopidae*). They have teeth on both the upper jaw and the vomer bone; the bodies of the vertebrae are cupped in front; the sternum is altogether cartilaginous; the sacral transverse processes are greatly expanded; the pupil of the eye vertical and the side of the foot is provided with a plate-like appendage supported by cartilage, from which they take their name. The spade-foot is found throughout the eastern United States, but is in most places rare and of very uncertain occurrence, appearing suddenly in great numbers and as suddenly disappearing some seasons and again being entirely absent. It lives in burrows, from which it issues at night or after long-continued rains to feed on insects. Early in the spring it breeds, the eggs being deposited in temporary rain-pools. If the season be a dry one, development of the tadpoles is much quickened by the drying up of the water, but in wet seasons the larval period is extended. Most remarkable is the voice, which is so loud as to astonish all who hear it produced from so small an animal. These toads are very noisy during the period of reproduction, but soon after become quiet and disappear. Another species (*S. couchii*) is found in Texas and Mexico, five or six more in the latter country and three other species belong to western Europe and the Mediterranean region. Consult Dickerson, 'The Frog Book' (new ed., New York 1914); Gadow, Hans, 'Amphibia and Reptiles' (in 'Cambridge Natural History' Vol. VIII, London 1901).

SPADE GUINEA, an English guinea having a spade-shaped shield bearing the arms on the reverse. They were coined from 1787 to 1799, inclusive.

SPAETH, spāth (Philip Friedrich) Adolph (Theodor), American Lutheran clergyman: b. Esslingen, Württemberg, 29 Oct. 1839; d. 2 June 1910. He was graduated from the University of Tübingen, 1861, was called to Zion's Church, Philadelphia, Pa., in 1864 and was pastor of Saint Johannes German Lutheran Church, Philadelphia, 1867-1910. He was also a professor in the Lutheran Theological Seminary and was president of the general council of the Evangelical Lutheran Church in North

America, 1880-90. His publications include 'Phœbe, the Deaconess' (1885); 'Faith and Life as represented by Martin Luther' (1887); 'Biography of Dr. Charles Porterfield Krauth' (1898).

SPAGHETTI, spa-gět'tī. See MACARONI.

SPAGNA, spān'yā, Lo, easel name of Giovanni di Pietro, Italian painter, active during the first quarter of the 16th century. He was born in Spain and hence the designation, by which he is generally known, "The Spaniard." He was a pupil of Pietro Perugino, whose name is frequently applied to Spagna's work and a contemporary of Pinturicchio and others of his school. He was a painter of some considerable talent and a contemporary of Raphael, whom he has been accused of imitating. He seems to have been a member of a guild or company of notable painters who worked together, so that it is difficult to distinguish his work from that of his fellows. Very little is known of his life. He lived in Spoleto in 1516, where his masterpiece 'The Madonna Enthroned' was painted. The National Gallery in London contains his 'Agony in the Garden,' which was formerly attributed to Raphael. Among his notable works are 'Coronation of the Virgin' (at Todi); 'Nativity' (in the Vatican); 'Madonna' (in the Louvre); 'The Nine Muses' (in the Capitol at Rome); altar-pieces and frescoes (at Assisi, Spoleto and neighboring places).

SPAGNOLETTO, spān-yō-lēt'tō, Lo. See RIBERA, JOSÉ.

SPAHIS, spā'hīs, or **SIPAHIS**, a part of the Turkish cavalry, which is said to have been organized by Amurath I, the founder of the janizaries; but which, since the organization of the Turkish army on the European system, has given place to regular cavalry. The spahis were composed of two classes; one with red, the other with yellow banners. The usual arms of the spahis were a sabre, a lance, a jereed (a dart about two feet long, which was hurled with great strength and skill) and a second sabre, or rather broad-sword, attached to the saddle. Some of them had bows and arrows and also pistols and carbines; but they made little use of firearms. The French call a body of light cavalry raised in Algeria by the name of spahis. The name sepoys, given to native troops in India by the British, is the same word.

SPAHR, spār, Charles Barzillai, American publicist and editor: b. Columbus, Ohio, 20 July 1860. He was graduated at Amherst, 1881 and studied later at Leipzig. He was associate editor of the *Outlook*, 1886-1903 and since February 1904 has been managing editor of *Current Literature*. He has published several articles on economic topics and is the author of 'The Present Distribution of Wealth' (1896) and 'America's Working People' (1900). Consult Abbott, Lyman, 'One Who Loved His Fellowmen' (New York 1905).

SPAIN (Lat. *Hispania*, Sp. *España*), a kingdom the territory of which in Europe embraces more than four-fifths of the Iberian Peninsula, the small islands near the coasts, the Balearic Islands and the territory of Llivia, locked in France and separated completely from the rest of Spain; in northern Africa the possessions of Ceuta and Melilla,

the islands of Peregil, Vélez de la Gomera, Alhucemas, Alborán and Chafarinas; off the western coast of Africa, the Canary Islands, and along or near that coast a continental district that, extending at the west of the Desert of Sahara between the capes Bojador and Blanco, is known as the Spanish Sahara and the territory of the Ifni River; and in the Gulf of Guinea the Islands of Fernando Pó, Corisco and Annobón, the islets Elobey Grande, Elobey, Pequeña, Banie, Leva and Bañe, and that part of the African continent denominated Spanish Guinea, on the Muni River. Spain also exercises a protectorate over the African coast from Cape Bojador to the southern frontier of Morocco. Situated in the southwestern part of Europe and separated from the main body of the European or Eurasian continent by the cordillera of the Pyrenees, the peninsular part of Spain extends from lat. 43° 27' 25" N. at Point Estaca de Vares to lat. 35° 59' 50" N. at the south point of Tarifa Island; from long. 3° 20' E. of Greenwich (7° 0' 28" E. of Madrid) at Cape Creus to 9° 15' W. of Greenwich (5° 37' 03" W. of Madrid) at Cape Toriñana. Its total area is given as 195,000 square miles, approximately, or (by Dirección General del Instituto Geográfico y Estadístico, 'Reseña Geográfica y Estadística de España' (Madrid 1912-14), 492,247 square kilometers, and its boundaries are: On the north the Cantabrian Sea or Bay of Biscay, France and the republic of Andorra; on the east the Mediterranean Sea; on the south the same sea, the Strait of Gibraltar and the Atlantic Ocean; on the west that ocean and Portugal.

Distinguishing physical characteristics are the high average elevation of the land above sea-level and the regularity of the coasts. The ratio of that part of the entire area lying below 1,600 feet to that part uplifted above 1,600 feet is approximately 23 to 36. In other words, more than three-fifths must be regarded as highlands, and the altitude of one-third of the highlands is over 3,200 feet. Excepting Switzerland, Spain is the highest of all European countries (mean altitude of the former 1,300 metres and of the latter 660 metres). It is even true that the mean elevation of the cordillera of the Pyrenees is greater than that of the Alps, although the latter has some peaks higher than the former; and the Sierra Nevada rises into the region of perpetual snows. In the centre of the country is a high region forming a secondary peninsula, so to speak, with a mean altitude of 2,000 feet, known as the meseta. The water-parting is in the eastern half of the country as a rule, the Ebro being the only Spanish river with a long course flowing into the Mediterranean. Excepting the Ebro Valley, then, the western slope is much more extensive and less abrupt than the eastern; and communication between the centre and the western littoral is naturally easier than between the centre and the Mediterranean; but Portugal has separated the most accessible maritime zone from the central highlands, and so Spain has kept an extensive littoral without any easy natural communication between it and the interior except the valley of the Guadalquivir. (See RIVERS).

The western slope is divided into five unequal bands by four mountain systems which

bound the great valleys of the rivers Duero, Tagus (both mainly Portuguese), Guadiana (the lower course of which partly in Portugal) and Guadalquivir; leaving at the north a narrow band which sends its waters directly to the Cantabrian Sea (Bay of Biscay) and is bounded by that sea on the north and the Cantabrian Mountains on the south. All these cordilleras have a fundamentally east and west direction in Spanish territory, but change abruptly to take a northwest-southeast direction when Portugal is reached, and to some extent create barriers or obstacles constituting the natural frontier of Portugal—so far as the boundary between the two nations can be regarded as natural, and not purely conventional.

In spite of the fact that it appears on first view to be characterized by exceptional unity in form and contours, Spain offers in the interior a great variety of geographical conditions; since nature has divided it into isolated regions essentially differing in climate, the geological composition of the soils, the flora, the fauna, and the character, customs and worldly possessions of its inhabitants. As a consequence of the exceptionally diverse geographical conditions, there are also marked differences in the density of the population of the several districts. Thus, from the periphery to the centre the density of the population decreases in such a fashion that we can say the inhabitants are distributed in concentric zones of different density, the minimum, with the exception of the arbitrarily located capital, being at the centre, which is the part of Spain that nature favors least of all.

Geology.—Extending like a bond of union between Europe and Africa, the Iberian Peninsula makes the impression of being the least European of the three great Mediterranean peninsulas: it announces Africa by the massive character of its forms and by the existence of its mighty central meseta. "It is," says an authoritative writer in the study by R. Douvillé, entitled 'La Péninsule Ibérique, on Espagne' (Heidelberg 1911), "a world apart, separated from Europe by the high Pyrenean barrier which cannot be surmounted easily except at the two extremities, separated from the Mediterranean world by the different coast ranges that now themselves form the shore and again leave only a narrow strip between themselves and the sea"—for example, the Valencian *huerta* and the plain of Taragon. It is indeed possible to give correct ideas of the main structural characteristics of Spain, but, as the same geologist cautions, we possess only relatively few precise notions concerning the constitution of the zones of its mountain-folds, despite the fact that the stratigraphy of a large number of its natural regions is known in detail, and several of the regions have even become classics for the geological student. Thanks to the labors of Léon Bertrand and Bresson, of the Andalusian commission, of Nicklès and of R. Douvillé, we are beginning to know with some precision the structure of the two border chains, the Pyrenean and the Sub-bétic or Penibético, the latter including the Sierra Nevada. The complexity of the corrugations of the ancient rocks of the Cantabrian chain has been brought

to light by Barrois, but as to all that relates to the inequalities of the central portion of the meseta, grouped together by Choffat under the name of the Lusitano-Castilian System, we are still left in uncertainty: their structure and exact age are wholly unknown. Moreover, the Bétic chain remains still unexplored, from the structural point of view.

With due recognition of the limitations just indicated we present the following general and brief account, deduced from the facts actually known.

The orientation of the outcropping strata in the centre and northwest is different from that in the regions of the Pyrenean, Catalanian and Bétic ranges. In the centre and northwest the outcropping strata—Silurian, for example—are aligned nearly southeast and northwest; in the Pyrenean, Catalanian and Bétic chains, on the contrary, the outcroppings in the main follow the direction of the mountain ridges (chainons) and are oriented approximately southeast by east and north-northwest or southwest and northeast. Thus we are dealing with systems of corrugations or folds that are essentially different. The southeast-northwest folds are those of the mighty crystalline and Paleozoic mass of the Iberian meseta; the others are those of the bordering chains, the Pyrenean, Catalanian and Bétic. These bordering chains have a nucleus formed, like the meseta, of Crystalline and Paleozoic rocks, but in addition they possess representatives of almost entire sedimentary series. They belong to the zone of Alpine folds; they have had a geologic history extremely different from that of the meseta; and they also differ among themselves, one from the other, the Pyrenean and Catalanian chains showing distinctly special formations while the Bétic chain shows types that are general and seen in the whole Mediterranean zone. The Catalanian chain strongly resembles in almost all respects the Pyrenean; but it probably formed a part, in some former epoch, of a mighty crystalline mass occupying a portion of the Mediterranean until submerged at an indeterminate period. Similarly, the Bétic chain appears to have been partially submerged at the time of those Pliocene movements which accompanied the opening of the Strait of Gibraltar. The meseta is bordered on the south and on the north by two great transverse inequalities, of which the most striking is the fault of the Guadalquivir, at present underlined by the depression in which flows the Guadalquivir River: a gigantic fracture that cut, as with a knife, all the outcropping strata. A happening probably of the same kind was associated with the profound depression of the Ebro Valley. But the mesozoic deposits which, at different epochs, have overspread the meseta, now hide all the northeast part of the Guadalquivir fault and the fracture of the value of the Ebro. These deposits are found to be more horizontal as one proceeds farther toward the interior of the peninsula. On the borders of the meseta they are slightly corrugated and form the Sierra del Moncayo and the Montes Universales which mark out the northeast border. The Sierra Morena has no geologic individuality. The depressions of the Guadalquivir and of the Ebro have been filled with Tertiary sediments; and

the same holds true of the lowest portions of the meseta, the two Castiles. In consequence of a general uplifting movement throughout the meseta, with reference to the level of the sea, the Tertiary sediments upon the meseta have been raised until they form now the high plateaux already described.

Rivers.—The northern slope extends between the Bay of Biscay and the Cantabrian Mountains. Here we find a long and narrow zone characterized by heavy rainfall upon extremely steep declivities—with the result that its rivers are torrents, without value for navigation. The eastern slope is divided into three parts, namely, the slope of the eastern Pyrenees, the Ebro Valley and the southeastern region. In the first part we find the Muga, Llobregat, Ter, Tordera, Gallá and Francolí. In the second part, which embraces almost one-sixth of the area of Spain, we find the Ebro and its affluents, the Zadorra, Ega, Aragón, Gállego, Segre, Cinca, Jalón, Calatayud, Huerva and Guadalupe. In the third part are the Júcar, Vinalopó and Segura. The Ebro, if we may judge from data supplied by history, was formerly navigable from its mouth even to Logroño; but it has suffered important changes, and canalization at two points became necessary. The Carlos Canal was cut through the delta formed by deposits of sand and projecting out into the Mediterranean; the Imperial Canal was constructed from a point 40 miles below Zaragoza (Saragossa) to Tudela. The western slope is, from the hydrographic point of view, most important of all, since in this wide zone are found the valleys of the great rivers Miño, Duero, Tajo (Tagus), Guadiana and Guadalquivir. The last-mentioned has always been of highest value for transportation; and in early historical times it was navigable far beyond Seville—even to Córdoba or Montoro. The southern slope is even narrower than the northern, and is the least important of all in a hydrographic sense; the rivers of this slope being characterized by short course and small volume. Here we find emptying into the Mediterranean, the Almería, Adra, Guadalfeo, Guadalhorce, Guadiaro; and, emptying into the Atlantic, the Guadalete. With a few important exceptions, then, all the rivers of Spain dash, rather than flow, along precipitous beds among deflecting mountains; their character is torrential, their courses sinuous. Consult Becker, J., 'El Medio Geográfico en la Historia de España' (*Boletín de la Real Sociedad Geográfica*, Tomo LVIII, Madrid 1916).

Mountains.—The study of Spanish orography concerns itself with the three exterior lines that mark the northern, eastern and southern slopes, and the other three that extend through the interior. The northern system, including the Cantabrian Cordillera and the Pyrenees, bounds on the north the central meseta and the Ebro Valley. According to the classification of the Geographical Institute of Madrid, this is followed by (2) the Iberian system, formed by mountain-masses which separate the central meseta from the Ebro Valley [on the northeast] and from the Mediterranean slopes; (3) the Central system, generally known as Cordillera Carpeto-Vetónica or Carpetana, which extends through

the centre of the peninsula and separates the mesetas of the two Castiles; (4) The system of the mountains of Toledo, extending east and west in the centre of the meseta of New Castile; (5) the Bétic Cordillera, between the great central meseta and the depression of the Guadalquivir and formed mainly by the Sierra Morena; (6) the Penibétic system, which extends from Cape Tarifa to the Sierra Nevada, including both, and shuts in the valley of the Bétis, or Guadalquivir, on the south.

Climate.—Extending approximately from lat. 36° N. to little less than 44° N., Spain forms a part of the southern region of the temperate zone, and would be endowed with a climate characterized by very distinctly marked seasons were such cosmic traits not greatly modified by various circumstances. We have already mentioned, among the geographical influences to which its climate is subject, the great heights and different orientation of its cordilleras and the varied configuration of its lands—such diversity of natural features of course affecting the atmospheric circulation and in part explaining sudden alternations of winds that are hot and damp with those that are cold and dry. But we must also remember that the north coasts, influenced by the Bay of Biscay, the western by the Atlantic Ocean, the southern and eastern by the Mediterranean Sea, experience particular effects which are far from being the same. Moreover, the influence of the Gulf Stream is felt especially on the northwest coast, and that of the Sahara in the south. It is, therefore, proper to emphasize Spain's climatological diversity: it is not possible to say that a well-defined climate prevails in or throughout any extensive region whatever, since there exist in the country, and sometimes almost side by side, all the mixtures from sub-tropical to Alpine. On the plains of New Castile and Estremadura, as in a large part of Andalusia, the climate in summer is rather fiercely torrid; in all the cordilleras one finds delicious valleys, of benign temperature; but the lands of Old Castile and León are characterized by harsh and prolonged winters. The annual rainfall, greatest in the northwest, especially Santiago, is slightly less at Saint Sebastian and Bilbao; about half as great at Coruña, San Fernando, Cáceres and Jaén; less than one-half as great at Málaga, Soria, Burgos, Huesca, Segovia and Barcelona; about one-third, or even less, at Sevilla, Murcia, Valencia, Granada, Alicante, Molina and Madrid; about one-fourth at León, Badajoz, Lérida, Cartagena and Valladolid; and at Salamanca and Zaragoza the annual rainfall amounts only to one-fifth or one-sixth of that which makes the Spanish northwest a beautiful green country.

Flora.—The diversities of temperature, etc., to which we have invited attention (see CLIMATE) occasion such a variety in the species of vegetation as no other country of Europe presents. For this reason Linnæus bestowed the title "India of Europe" upon Spain—which, indeed, in all historical ages has been considered the botanist's land of promise although the growths of forest and field are checked by the extreme aridity of the meseta. The number of indigenous species positively known to exist in Spain exceeds to-day 7,100, without counting those varieties and forms about which doubt is

still entertained. This wealth becomes even more manifest on comparing it with that of other countries. Thus, if we reckon at 10,000 the number of species of vascular plants in Europe as a whole, about 5,400 of them exist in Spain, 4,225 in France, about 5,000 in Italy, including Sicily, and slightly more than 1,600 in England. Even in the small province of Madrid there are, despite the aridity of its plains, approximately 2,000 species. And if we compare the numbers of the *exclusive* species we shall find that 1,200 endemic species exist in Spain (about 22 per cent of the vasculars); in Italy about 300 or about 6 per cent of its flora). In France the strictly indigenous species number about 100 (or, say, somewhat more than 2 per cent). We may estimate very closely the affinity of the Spanish flora with that of other lands as follows: Of spontaneous vascular species in Spain 60 per cent are represented also in the other European floras; 25 per cent are very similar to those of northern Africa; slightly more than 13 per cent Spain possesses in common with Asia; with South America not more than 7½ per cent; with North America less than 3 per cent; 2½ per cent with tropical and southern Africa; and with Oceania only about five species per mille.

Fauna.—Like that of all the rest of the Palearctic-Mediterranean subzone, the fauna of Spain is extensive and extremely varied. A leading work on the crustaceans entitled 'Materiales para la Fauna Carcinologica de España,' by Sr. Odón de Buen, says that the Mediterranean region is richer than the "Celtic" [northern and northwestern] in the carcinological fauna. D. Francisco García Solá, in his *Memoria* prepared for the Central Commission of Fisheries of the Navy Department, calls attention to the circumstance that the waters of the east and south coasts contain many varieties of fish for the reason that the Mediterranean is "the great natural breeding-place of the Atlantic and perhaps of other more remote seas." The number of specific forms or species of insects in the entire peninsula is reckoned at more than 160,000. The most common reptiles are *Vipera latastei*, *Tropidonotus viperinus*, *Rhinechis scalaris*, *Psammotromus hispanicus* and *Lacerta muralis*. The avifauna includes particularly some arctic species in the high mountains, great numbers of maritime and river-birds, and (in the southeast) several species of vultures and falcons. Mammals are uncommonly well represented, in the Perisodactyl order, by the genus *Equus*, and by ruminants of the Artiodactyl order. The order of Carnivora is represented by the *Ursus arctos*, by Spanish varieties of the genus *Canis*, the *Canis lupus*, the *Canis vulpes*, etc.

Forestry.—The mountains and many tracts of the table-land are in general very scantily supplied with trees and a want of timber, both for fuel and economical purposes, is severely felt in many quarters. The finest forests are on the western offshoots of the Pyrenees and in the mountains of Asturias. The more remarkable trees are the Spanish chestnut and several varieties of oak, and in particular the cork-oak.

Fisheries.—This industry employs 15,512 boats, of which 791 are steamers, and 88,150 fishermen. The catch in a recent year aggre-

gated 148,978 tons valued at \$18,166,650. Cod, sardines and tunny fish are the most important catches. Sardines and fish-preserves are prepared in 677 factories employing 19,320 workmen and having an annual product valued at \$12,634,878.

Agriculture.—It is remarkable that Spain, though one of the most naturally productive, is also one of the least cultivated of the countries of Europe. More than a third of the land capable of profitable cultivation is allowed to lie waste, and the system of agriculture pursued is far behind that of any other European country. The finest agricultural district is Valencia, where both rice and corn are grown far beyond the wants of the actual population, and furnish large supplies to those parts of the interior which are less favorably situated. After Valencia, Catalonia, Murcia, and some of the northern provinces, raise the largest quantities of grain. The more important crops are wheat, rice, maize, barley and legumes. The culture of the vine is general, and great quantities of wine are made, both for home consumption and exportation. The demand for the latter is chiefly confined to sherry and the sweet wines of Malaga and Alicante. A considerable part of the grapes grown are dried and exported in this state, especially from the port of Malaga. Nuts, common and pistachio, walnuts and chestnuts grow in such abundance as to form important articles of trade. In the warmer districts the olive, sugarcane and cotton-plant are partially cultivated. Fruits are extremely abundant and include in addition to apples, pears, cherries, piums, peaches and apricots, the almond, date, fig, orange, citron and pomegranate; and in the lower districts of the south, the pineapple and banana. Hemp and flax are extensively grown in Aragon, and Galicia, and esparto grows in abundance, more especially in Valencia and Murcia, where it is in extensive demand for making ropes, mats, baskets, etc., besides being exported. The mulberry thrives well, and is largely cultivated for rearing silkworms in Valencia, Murcia and Granada. Other vegetable products are saffron, licorice and barilla. Much of the higher part of the central tableland, however, presents a very sterile appearance, having a thin stony soil and a covering of heath and scanty pasture; still extensive tracts which might be advantageously cultivated are left almost in a state of nature, to be roamed over by cattle, sheep, goats and swine.

Of Spanish soil 88.45 per cent is classed as productive; of this 35.5 per cent is devoted to agriculture and horticulture, 2.5 to vineyards, 2.9 to olives, 22.2 to fruits and 25.3 to native grasses. There are 3,426,083 separate holdings which pay a property tax. The acreage and yield of the chief crops in 1918 was: wheat, 10,348,537 acres, yield 73,868,578 cwts.; barley, 4,258,892 acres; 39,406,852 cwts.; oats, 1,524,453 acres, 8,846,606 cwts.; rye, 1,839,752 acres, 15,466,774 cwts.; maize, 1,182,742 acres, 12,264,502 cwts.; rice, 111,807 acres, 4,152,968 cwts.; beans, 498,385 acres, 4,012,110 cwts.; kidney beans, 794,607 acres, 3,622,040 cwts.; peas, 138,607 acres, 645,356 cwts.; chick peas, 562,267 acres, 2,334,548 cwts.; tares, 457,165 acres,

1,748,414 cwts.; vetches, 159,472 acres, 996,522 cwts.

In the same year 3,292,925 acres were under vines. The production was 8,400,104,240 pounds of grapes, yielding ordinary red and white wines to the extent of 496,487,596 gallons. About 3,760,000 acres were under olives and yielded 1,986,930 tons of olives and 385,053 tons of oil. The recent live-stock census showed 557,676 horses; 1,042,894 mules; 923,996 asses; 3,233,200 cows; 17,227,019 sheep; 4,181,942 goats; 3,929,449 pigs and 5,400 camels (Canary Islands).

Stock Raising.—Among domestic animals the horse, descended from breeds which the Moors had introduced, was long celebrated throughout Europe, but has in recent times declined in reputation, though Andalusia still boasts of many fine animals. The mule is generally preferred to the horse, both for carriage and draft, and is extensively reared in New Castile. Both it and the ass are generally of a very superior description. Horned cattle are generally inferior and not numerous; only in a few districts are cows kept for dairy purposes; bulls, in great demand for the national amusement of bull-fights, are reared in greatest perfection in Andalusia. The favorite stock is the sheep, a considerable proportion of which belongs to the celebrated Merino breed, to which almost all the other breeds of Europe are more or less indebted for improvement. Goats also are very numerous, and in their flesh, milk and cheese furnish the favorite food of the inhabitants. Swine are kept in large herds in some parts of Estremadura and in some of the northern provinces, where they roam at large in the forests. See AGRICULTURE section.

Manufactures, Mining, Commerce, etc.—In the Middle Ages the manufactures of Spain, particularly along the coasts of the Mediterranean, were in a flourishing condition and found an extensive demand, particularly in the Levant and other parts of the East. With the expulsion of the Moors the branches which they had specially fostered sunk rapidly into decay and have never been revived. New demands, however, arose in the West and Spain, as the mother country, reserving to herself the sole supply of the colonies, was able, for that purpose alone, to carry on a number of lucrative manufactures. The loss of these colonies, putting a sudden stop to the demand, was followed by their almost as sudden extinction. The circumstances of the country since have been the most unfavorable that can be conceived to the progress of any branch of regular industry and hence the only manufactures of any importance are to be found in a few of the larger towns, especially Barcelona. Spain is comparatively rich in minerals. Iron is plentiful in Huelva, Navarre, Oviedo, Santander, Seville and Vizcaya; copper in Córdoba, Huelva and Seville; coal in Córdoba, Geronas, Leon, Oviedo and Valencia; zinc in Guipúzcoa, Murcia, Santander and Vizcaya; cobalt in Oviedo; lead in Almería Jaen and Murcia; manganese in Huelva, Oviedo and Seville; quicksilver in Ciudad Real and Oviedo; silver in Guadalajara; soda in Burgos and phosphorus in Cáceres and Huelva. Platinum has also been found in small quantities. A recent

industrial census showed 127,556 men, 3,917 women and 20,273 boys and girls under 18 employed in connection with the mining industries. In 1917 the total value of the mineral output was \$97,692,858, made up as follows:

MINERAL	Quantity produced in metric tons	Value
Anthracite.....	324,756	\$2,473,373
Asphalt.....	1,817	4,274
Mercury.....	18,706	701,064
Sulphur.....	84,979	1,580,921
Zinc.....	123,486	1,830,286
Copper.....	1,901,340	12,295,912
Tin.....	77	21,160
Phosphorite.....	28,148	137,019
Iron.....	5,551,071	7,925,115
Iron pyrites.....	376,918	3,898,320
Coal.....	5,042,213	48,097,335
Lignite.....	637,841	4,690,024
Manganese.....	54,474	419,824
Silver.....	96	15,654
Lead.....	240,368	12,305,766
Argentiferous lead.....	13,218	6,592
Salt.....	309,413	368,172
Wolfram.....	546	328,856

There are large manufactures of cottons, Catalonia being the principal centre of this industry. There were reported at the last industrial census, 742 establishments employing 68,300 looms and with 2,614,500 spindles. The woolen industry occupies 8,800 looms and 662,000 spindles. There are 144 paper mills and 37 glass-making factories. Corks are also an important product. In a recent year 51,089 tons were manufactured having a value of about \$9,000,000.

Imports in 1918 were valued at \$121,970,385 and the exports \$189,585,420. In that year the chief classes of imports and exports were as follows:

CLASS	1918	
	Imports	Exports
Stone, glassware, pottery.	\$5,799,220	\$15,042,840
Minerals, metals and metal goods.....	3,998,330	29,692,450
Drugs and chemicals.....	7,236,800	12,262,950
Cotton and cotton manufactures.....	20,506,420	23,577,800
Other vegetable fibres, etc.....	3,506,220	1,909,715
Wool, hair, and their manufactures.....	6,327,680	17,923,785
Silk and silk manufactures.....	5,210,655	1,401,495
Paper and paper goods.....	1,704,640	2,984,515
Timber and timber products.....	2,668,915	7,102,220
Animals, animal products.....	9,934,560	7,302,710
Machinery, vehicles, etc.....	11,888,390	4,103,145
Food stuffs, including grains, sugar, wine, etc.....	25,619,315	66,656,980
Miscellaneous.....	3,788,025	2,721,200
Gold (bar and coin).....	6,771,740	40,310
Silver.....	57,040	1,863,305
Tobacco (special).....	6,795,310	
Packing.....	157,125	
	\$121,970,385	\$189,585,420

The value of all wine exported in 1918 was \$18,625,685. In 1917 the United States was

the leading country importing goods into Spain with a total value of \$155,339,800. In the same year France took more Spanish goods (\$117,653,600) than any other country. The United Kingdom was second with \$40,413,000 and the United States third with \$21,225,600. Cuba, Porto Rico and the Philippines also (\$117,653,600) than any other country. The customs receipts and post dues amounted to \$23,935,235 in 1918.

Art.— See SPANISH ART.

Language and Literature.— See SPANISH LANGUAGE; SPANISH LITERATURE.

Spanish Educational System.— The present Spanish school system dates from 1900. The centres of education are divided into three categories: primary, secondary, or preparatory, and superior, or university. The first is supplied by the municipalities or by licensed private schools; the second is directly controlled by the state and consists of institutes and private colleges under governmental supervision. The instruction in the preparatory schools consists of two sections, arts and sciences, and the baccalaureate is given in these institutions and not in the universities. The third class is made up of the universities, all supported by the state. In the larger cities, moreover, are normal colleges, commercial and language schools and institutions for the primary instruction of adults. The system is well planned and based on good laws but the lack of finances makes even the number of primary schools inadequate in small towns and rural districts. The whole system is under control of the Minister of Public Instruction and Fine Arts.

Spain is divided into 11 university districts with uniform organization, which are in order of rank: Madrid, Barcelona, Granada, Oviedo, Salamanca, Santiago, Seville, Valencia, Valladolid, Murcia and Saragossa. The largest is Madrid with more than 6,500 students. At the head of each university is a president who has charge not only of the institution proper, but of all the schools in his district. The faculties are presided over by deans subordinate to the president. Professors obtain their chairs in competitive examinations held publicly when a vacancy occurs. Besides the 10 universities maintained by the state are three controlled by religious orders; but they are not officially recognized and to obtain credit for his work in these institutions a student has to pass the prescribed examinations in the state universities. In the near future the government is to establish another university in the Canary Islands, now a province of Spain.

The government institutes or preparatory schools are grouped in 10 sections corresponding to the 10 universities of the state and are further subdivided into provincial or local institutes according to their importance.

University instruction embraces the five faculties of philosophy and letters, sciences, law, medicine and pharmacy, all of which include several subdivisions. Theology is not now taught in the universities although members of the clergy and religious orders often hold important chairs in them. All five faculties exist and the doctorate is conferred only in the Central University of Madrid. Modern languages are not taught in the universities but in certain special schools. French is taught in the institutes.

To obtain the doctorate in medicine seven years' study are necessary; this is the longest course. The degree of licentiate is conferred after six years' study in law, five in pharmacy and four in the other faculties. The doctorate and the licentiate are given in all faculties. These two are the only university degrees. The former is similar to that given in American universities, while the latter is an intermediate stage between the American degree of bachelor and master. The student must needs have attained the age of 16 and received the baccalaureate in arts or sciences before permitted to enter the universities as a candidate for a degree. The students are divided into two classes: official or free (*oficial o libre*). The official students must attend classes and stand examinations, somewhat less rigorous than those given to the students of the latter class, who do not attend classes and matriculate only for the examinations at the end of the year. The examinations are both oral and written and a second series have to be passed when the student applies for his degree. This division of the students into official and free also applies to the institutes of the state. A student may be official or free at his option, or he may be a free student in some subjects and official in others, or free in all subjects and attend the class lectures with the permission of the professor in charge. This arrangement exists for the convenience of the student who receives his instruction from a tutor or who attends an institution conducted by the Church. No distinction is made between the sexes in governmental schools and women have never been refused admittance to the universities. The number of women taking university courses, however, is negligible and in 1914 there were only some 25 in the University of Madrid.

Certificates signed by the examining board of three professors are given to the student for each subject he passes; the three passing grades are "approved," "honorable mention" and "excellent," and the certificates are marked accordingly. A student who receives "excellent" (*sobresaliente*) in his subjects is entitled to the remission of part of his fees for the following academic year. All students, official and free, pay about 35 pesetas (\$6.65) for each subject in which they are examined. Students particularly successful in their university work are sometimes, but not always, granted government grants for study abroad. According to a royal decree of 19 Sept. 1913 "titles which in their respective countries give the holder entrance without examination into the universities will be valid in Spain." Owing to Spain's refusal hitherto to recognize foreign degrees, many thousands of students from Latin America are studying in other lands. Since 1902 the Spanish government has sent scholars, teachers and professors to foreign countries to study. Since 1910 there has existed a Board of Scientific Research (*Junta para ampliación de estudios*), which connects the work done abroad with the organization of new laboratories in Spain, and publishes works showing the results obtained. This board has started the foundation of Halls of Residence for students where an important educational and a certain amount of scientific work is done. This board expends about 800,000 pesetas (\$154,000) per annum. A Hall of Residence for

women students was opened in Madrid in 1916.

The government spends about \$8,000,000 annually on its primary school system. There are 26,108 public and 5,669 private schools, the total number of pupils being 2,604,308. There are 58 institutes or middle-grade schools with 52,015 pupils. The 11 universities are attended by 32,683 students. The educational system and fine arts departments cost the government \$15,000,000 in 1918.

Religion.—The state religion is Roman Catholic. The Church is governed by 9 archbishops and 47 bishops, but two of the former and five of the latter have their dioceses beyond sea. The number of parishes is about 20,498. In 1837 all the convents of monks, with a few exceptions, were suppressed and their revenues, subject to a provision for existing members, confiscated to the state. At the period of extinction the number of convents was 1,940, with 30,906 monks; there are still 790 convents with 9,339 monks and 3,010 with 39,709 nuns. Since the last revolution toleration of all denominations has been decreed. The whole population of Spain is Roman Catholic, except about 30,000 of whom 7,000 are Protestants and 4,000 Jews, Rationalists, etc. The State supports the clergy of whom there are over 35,000. About \$8,000,000 are expended annually for this purpose. Relations between Church and State are regulated by the Concordat of 1851.

Army and Navy.—Military service is compulsory. The total term of service extends over 18 years. According to the law enacted in 1912 this period is divided into: one year, *Reclutas en Caja* (recruits in deposit); three years, active army (first standing); five years, active army (second standing); six years, reserve; and three years, territorial reserve. A general army staff was created in January 1916. For army administrative purpose, Spain is divided into eight territorial districts, each under a captain-general. District one to six inclusive each furnish two divisions, the districts seven and eight, one division. A division comprises two infantry brigades, each consisting of two regiments of three battalions, one regiment of cavalry, and one regiment of field artillery of six batteries. Batteries have four guns. The peace establishment of the army was fixed at 190,228 men of all ranks for 1918. In addition to the organization outlined above, which would develop a war strength of about 1,400,000, there are the Guardia Civil and the Carabineros. The former is a police force, and the latter a species of coast guard or revenue police. The Guardia has a strength of 18,000 infantry and 2,500 cavalry; the Carabineros 13,000 infantry and about 500 cavalry. Outside of Spain there are three military districts—Morocco, the Balearic Islands and the Canaries. In the two last-named the forces are recruited from the islanders but in Morocco the troops are Spanish and are always on a war footing. The African (Morocco) establishment totals about 70,000 men. The Mauser 275, model of 1893 is the infantry arm. Schneider Canet 14½ pr. of 19.106 that of the field artillery.

There is a military aviation school at Cuatro Vientos, near Madrid. There are military

wireless stations at Carabanchel (range 540 miles), Barcelona (430 miles), Melilla, Celta, Tetuan, Bilbao, Valencia (of 320 miles each), Almeria, Larache (220 miles each), Mahon (Balears) and Coruña. The military budget for 1918 aggregated \$53,000,000, of which about \$20,000,000 was for the Moroccan establishment.

The old navy was about totally destroyed or captured in the war with the United States, but in recent years naval construction has somewhat reinstated Spain in her old position. The navy at present has three dreadnoughts of 15,460 tons displacement each and are armed with eight 12-inch, 20 4-inch and six smaller rifles, also two torpedo tubes. The horsepower of each vessel is 15,500 and the speed 19½ knots per hour. There is also one old battleship, the *Pelayo* of 9,890 tons. There are seven cruisers, totaling 33,000 tons, also 13 destroyers and 24 modern torpedo boats, and a few gunboats. In 1915 a new construction program was inaugurated calling for four cruisers, six destroyers, 28 submarines, three gunboats, 18 coast-defense vessels, submarine mines, repair docks, etc., at a cost of \$55,000,000 to be completed in six years. Spain has 10 submarines. The strength of the navy in 1918 was fixed at 11,091 sailors, 4,190 marines and 1,662 officers.

Money, Weights and Measures.—By a decree of the Cortes in 1868 a new monetary system was introduced into Spain, according to which accounts are kept in *centesimos* and *pesetas*: 100 centesimos = 1 peseta = \$0.19; or one franc. The gold coins are pieces of 100, 50, 25, 20, 10 and 5 pesetas; the silver coins are pieces of 5, 2, 1 pesetas and 50 centesimos. The bronze coins are pieces of 10, 5, 2 and 1 centesimos. The weights and measures are precisely the same as those of France, with no other change than a slight one of names, the *metre* becoming the *metro*, the *litre* the *litro* and so on. The old system is still in use in many places. Its chief weights are the *Quintal* = 220.4 pounds; the *libra* = 1.014 pounds; liquid measures are the *arroba* = 3½ gallons for wine and 2¾ gallons for oil; the square *vara* = 1.09 vara = 1 yard; dry measure, the *fanega* = 1½ imperial bushels.

Communications and Shipping.—Trade labors under great disadvantages from the want of proper means of communication. The roads, except the royal roads (*caminos reales*), are generally wretched; the rivers, though numerous, are ill fitted for navigation; and though in recent times much has been done in constructing railways and tramways, much more is still required. Hence the foreign trade is almost necessarily confined to such articles of raw produce as are raised in greatest abundance and can be most easily conveyed to a seaport. The length of railways in Spain is 8,993 miles (14,988 kilometres), of which 6,880 miles are of 5.48 foot gauge (1.67 metres) and 2,106 miles of varying gauges, but mostly of 3.28 foot gauge. About seven miles are cogwheel and funicular lines. About 71,000,000 passengers were carried in 1917 and 35,500,000 tons of merchandise. All roads are in the hands of private companies, but nearly all are subsidized by the government. The receipts of the Post-Office Department in 1916 were

\$7,599,760 and the expenses \$3,910,655. In that year it handled 190,733,150 letters and post-cards and 280,351,621 printed papers, samples, etc. There are 6,792 post-offices. Spain has 64,832 miles of telegraphs, which in 1916 carried 16,705,945 messages. The system has 2,435 offices. There are 141 urban telephone systems and 202 interurban circuits, with a total of 48,410 telephone stations. There are 10 wireless stations controlled by a single company.

The Spanish merchant marine consists of 495 steam vessels of 749,548 tons net and 85 sailing vessels of 31,209 tons net. In 1918 there entered with cargoes at Spanish ports 5,857 vessels of 5,060,937 tons and 6,618 vessels in ballast of 3,684,747 tons. In the same year the total clearances were 13,836 vessels of 7,203,843 tons of which 12,595 vessels of 6,700,452 tons were with cargoes. Of the vessels entered 9,699 of 5,607,185 tons were Spanish; of the clearances 11,120 of 4,093,436 tons were of Spanish registry.

Government.—Up to 1868 the government of Spain, which was that of a hereditary constitutional monarchy, was regulated by a constitution adopted in 1837, and subsequently modified in 1845. After the deposition of Isabella II a new constitution was drawn up by the Cortes, elected by universal suffrage. This constitution bore date 1 June 1869, and modified considerably the previous one. According to it, "all powers emanate from the nation. The power to make laws resides in the Cortes. The sovereign sanctions and promulgates the laws. The executive power resides in the sovereign, who exercises it by means of ministers. The tribunals exercise the judicial power." After the abdication of King Amadeo in February 1873, Spain changed its form of government to that of a federative republic, until the proclamation, as king, of Alfonso XII., 31 Dec. 1874, when the constitution of 1869 was again brought into force. A new constitution, however, was proclaimed in 1876, when certain amendments were introduced. According to the enactments at present in force Spain is governed constitutionally, the executive power residing in the king, the legislative in the king and Cortes (or parliament) conjointly. The Cortes consists of two independent bodies or bodies of equal authority, the Senate and the Congress. The members of the Senate form three classes, namely, senators in their own right, not to exceed 80 in number; life senators nominated by the crown, 100 in number; and elected senators, 180 in number. The senators in their own right include royal princes who have attained their majority; grandees of the kingdom who are in possession of an income of 60,000 pesetas or about \$12,000; captains-general in the army, admirals of the navy; the archbishops, the patriarch of the Indies, the presidents of the council of state, the supreme tribunal and several other similar functionaries. The elective senators are chosen by the corporations of state, such as provincial legislatures, universities, the ecclesiastical bodies, etc., and the citizens who are the largest payers of state burdens, and this portion of the Senate is renewed by one-half every five years or altogether when the body is dissolved by the sovereign. The Congress or second legislative body, is to comprise at least one deputy to

each 50,000 of the population. The Cortes must meet each year, and its sessions are to be convoked, suspended or closed by the king. No project can become law until after it has been voted in both bodies. Projects of finance or taxation must be presented to the Congress before being submitted to the Senate. Voting is compulsory for all males over the age of 25 with a few exceptions. All such voters must be registered on the voting list and must possess full civil rights. Members of Congress must be 25 years of age and are re-eligible indefinitely, the election being held quinquennially. There are 417 deputies. Neither senators nor deputies receive any compensation.

Local Government.—The various provinces and communes are governed by their own municipal laws with local administration. Every commune has its own elected *ayuntamiento*, consisting of from five to 50 *regidores* or *consejales* and presided over by the *alcalde*, who in the larger towns is assisted by several *Tenientes Alcaldes*. The entire municipal government, with power of taxation, is vested in the *Ayuntamientos*. Half the members are elected every two years and they appoint the *Alcalde* from their own body. Members cannot be re-elected until after two years. Each province has its *diputacio provincial* or parliament, whose members are elected by the *ayuntamientos*, and in which are vested large political powers. It meets annually, and is permanently represented by the *Comision provincial*, a committee of its members, appointed every year. Neither the national executive nor the Cortes have the right to interfere in the established municipal and provincial administration except in the case of the action of the *Diputaciones Provinciales* and *Ayuntamientos* going beyond the locally limited sphere to the injury of the general and permanent interest. Pressure is often brought to bear on local elections by the central government.

Finances.—The revenue, raised chiefly by direct and indirect taxation, stamp-duties, government monopolies, colonial revenue and income from state property, amounted in 1919 to 1,648,800,068 pesetas (\$329,760,013) and the expenditure to 2,065,065,606 pesetas (\$413,013,121). Of the latter the public debt absorbed \$100,663,261, the Ministry of War, \$87,232,469, the Ministry of the Interior, \$44,000,000 and the Royal Household, \$1,840,000. The National Debt of Spain on 1 Jan. 1919 was \$1,884,317,207.

Population.—Formed by amalgamation of races or peoples as distinct as the Iberian, Celt, Phœnician, Greek, Carthaginian, Hebrew, Roman, Germano-Slav and Arabian, the population of Spain is endowed with characteristics which it is important to consider in connection with the development, or retardation of development, of the country; and that portion of the subject will, accordingly, be taken up in the section *History*. At present we note the total number of inhabitants (estimate in round numbers for 1917 about 20,376,000) and their distribution among the provinces, possessions and chief cities. The following table has been prepared with great care, but we think it impos-

sible to achieve more than approximate accuracy in every item.

PROVINCES	Number of inhabitants	Area in square miles
Álava.....	98,000	1,175
Albacete.....	240,000	5,737
Alicante.....	500,000	2,185
Almería.....	385,000	3,360
Avila.....	212,000	3,042
Badajoz.....	620,000	8,451
Baleares.....	330,000	1,935
Barcelona.....	1,164,000	2,968
Burgos.....	350,000	5,480
Cáceres.....	416,000	7,667
Cádiz and Ceuta.....	476,000	2,834
Canarias.....	450,000	2,807
Castellón.....	323,000	2,495
Ciudad Real.....	400,000	7,620
Córdoba.....	506,000	5,299
Coruña.....	684,000	3,051
Cuenca.....	276,000	6,636
Gerona.....	326,000	2,264
Granada.....	534,000	4,928
Guadalajara.....	213,000	4,676
Guipúzcoa.....	237,000	728
Huelva.....	327,000	3,913
Huesca.....	249,000	5,848
Jaén.....	547,000	5,203
León.....	396,000	5,936
Lérida.....	289,000	4,690
Logroño.....	189,000	1,946
Lugo.....	483,000	3,814
Madrid.....	879,000	3,084
Málaga.....	529,000	2,812
Murcia.....	616,000	4,453
Navarra.....	317,000	4,055
Orense.....	424,000	2,694
Oviedo.....	701,000	4,205
Palencia.....	197,000	3,256
Pontevedra.....	504,000	1,695
Salamanca.....	337,000	4,829
Santander.....	322,000	2,108
Segovia.....	170,000	2,635
Sevilla.....	618,000	5,428
Sovia.....	158,000	3,983
Tarragona.....	338,000	2,505
Teruel.....	287,000	5,720
Toledo.....	427,000	5,919
Valencia.....	885,000	4,150
Valladolid.....	287,000	2,922
Vizcaya or Biscay.....	388,000	836
Zamora.....	275,000	4,097
Zaragoza.....	450,000	6,726
Possessions in the Gulf of Guinea.....	24,000	Uncertain
Possessions on north and north-west coast of Africa.....	23,000	
Totals.....	20,376,000	194,783

The cities with a population of more than 29,000 each were in 1917: Madrid, 600,000; Barcelona, 588,000; Valencia, 234,000; Sevilla, 159,000; Málaga, 137,000; Murcia, 126,000; Zaragoza, 112,000; Cartagena, 103,000; Bilbao, 94,000; Valladolid, 72,000; Lorca, 71,000; Palma, 68,000; Cádiz, 68,000; Córdoba, 67,000; Santander, 66,000; Santa Cruz (Canary Islands), 64,000; Las Palmas, 63,000; Jerez, 63,000; Alicante, 56,000; Jihon, 56,000; Oviedo, 54,000; San Sebastian, 50,000; Almería, 49,000; Coruña, 48,000; Linares, 39,000; Badajoz, 36,000; Alcoy, 34,000; Vitoria, 33,000; Castellón, 33,000; Burgos, 32,000; Salamanca, 30,000; Pamplona, 30,000; Jaén, 30,000; Huelva, 30,000.

Ethnology.—The inhabitants of Spain consist chiefly of Spaniards proper, composed of a mixture of ancient aborigines, Romans, Visigoths, Vandals and Suevi; but partly also of three other distinct races—Basques, occupying the provinces to which they give their name and forming about $\frac{1}{4}$ of the whole population; Moors who, in the general expulsion of their countrymen, found refuge in several valleys in the kingdom of Granada and the Castiles, and whose descendants, unmingled with the other inhabitants, are still living there to the number of about 60,000; and Gitanos or gypsies,

who are found diffused over all parts of the Peninsula. The Spaniards proper, to whom only it is necessary here to advert, are of middle stature, well formed, of a sallow hue, sharp features, dark hair and keen black eyes. In diet the Spaniards are frugal and temperate. Their wants being thus comparatively few, are easily satisfied and furnish no strong stimulus to exertion. Indolence accordingly is a prevailing vice, and the highest ambition generally felt is to be able to live without doing anything. In their intercourse with strangers they are reserved, taciturn and stand much upon their dignity, afraid apparently of its being encroached upon by undue familiarity; but on finding what they conceive to be their true place properly recognized, they lay aside their restraint, form strong attachments and become the most agreeable of companions. With their natural indolence there is a strange mixture of enthusiasm, and when their passions are once roused there are few extravagances or excesses of which they are not capable. In favorable circumstances this part of their character has often manifested itself in chivalric exploits.

History.—Spain was known to the Greeks and Romans as *Spania*, *Hispania* and *Iberia*. The most ancient inhabitants of Spain appear to have been the Iberians, who also extended beyond the Pyrenees into Gaul as far as the Rhone. To these afterward were joined certain tribes of Celts, who succeeded in making a settlement for themselves in the country after sanguinary contests with the aborigines. In process of time the two races were amalgamated into one and went under the common appellation of Celtiberians. These occupied principally the high table-land in the centre of the country. The other parts were occupied by tribes of Iberians and Celts who had never intermingled. Pure Iberian tribes, from whom are descended the modern Basques, were to be found in the Pyrenees and on the coasts, while the unmixed Celts inhabited the northwestern corner of the country, corresponding to modern Galicia. The Phœnicians were the first civilized nation who made a descent on the peninsula and founded settlements there. Somewhat later the Greeks made their appearance, and among other colonies founded Saguntum. But more important than any of these were the colonies established by the Carthaginians. The history of Spain, indeed, only properly begins with the Carthaginian invasion, about 238 B.C. Previous to that almost all that was known of the country was the existence of the two commercial states of Tartessus and Gades, both in the west. The former of these, supposed to have been the Tarshish of Scripture, was much visited by Phœnician ships by reason of its mineral wealth. After the First Punic War the Carthaginians began to establish themselves in Spain; large tracts of territory were brought under their sway by Hamilcar (238–229), and again by Hasdrubal (228–221); and among the cities founded by them was New Carthage, the modern Carthage, which soon became a celebrated emporium. The subjected territory extended as far north as the Iberus (Ebro). Pressed by the Carthaginians, the Greek colonies of Saguntum and Emporizæ applied for aid to the Romans, who already had had their jealousy roused by the successes of their great rival. The

Romans interfered, and a treaty was then concluded between the two great powers, in terms of which the Carthaginians bound themselves not to extend their conquests beyond the Iberus. The city of Saguntum was on the west side of the river, but under Roman protection, and the capture of it by Hannibal in 219 was the immediate cause of the Second Punic War, which was partly carried on in Spain, and which in 206 caused the total expulsion of the Carthaginians from the peninsula. The Romans now undertook the subjugation of the entire country, but in this they did not completely succeed until after a war of about 200 years' duration, in which the exploits of the Lusitanian Viriathus, the heroic resistance and final downfall of Numantia (133), and the temporary independence of a part of the country under the gallant Setorius (84–73) form brilliant episodes. The Cantabrians, Asturians and other tribes in the mountains of the north were the last to yield, but were finally subjugated by Augustus and his generals, and Spain was converted into a Roman province. Previous to this the peninsula had been divided by the Romans into two parts, an eastern and a western, separated from each other by the Iberus, called respectively *Hispania Citerior* and *Hispania Ulterior*; but Augustus made a new division of the country, forming it into three provinces—*Tarraconensis*, *Bætica* and *Lusitania*. *Tarraconensis* and *Lusitania* were erected into imperial provinces and administered by legates; while *Bætica*, which still remained for a long time a senatorial province, was placed under the authority of a proconsul invested with civil authority only. Until the reign of Antoninus Pius, who granted to all his subjects a uniform constitution and laws, the cities of Spain were ruled by different laws. These and other measures made Spain one of the most flourishing provinces of the empire, and a centre of Roman civilization. Some of the most distinguished Latin writers under the empire were natives of Spain, such as the two Senecas, Lucan, Martial, Quintilian and others. Christianity was early introduced into Spain, and after the conversion of Constantine the Great became the dominant religion there. The disorganization and confusion consequent upon the fall of the Roman Empire facilitated the conquest of the country by the Vandals, who made themselves masters of a part of southern Spain, which from them received the name of *Vandalusia* (now *Andalusia*); the Suevi, who established themselves in the region now known as Galicia; and the Alans, who gained possession of Lusitania, now Portugal. These, however, were soon afterward attacked by the Visigoths, who, after many years' struggle, succeeded in reducing the whole peninsula to their sway. The Vandals of *Andalusia*, unable to withstand them, withdrew into Africa in 428, and from 467 to 484 the great Euric extended the kingdom of the Visigoths by the expulsion of the Romans and gave them their first written laws; while Leovigild in 585 overthrew the kingdom of the Suevi in Galicia. Under Leovigild's successor, Reccared I, the introduction of the Catholic faith in 586 gave the corrupt Latin language the predominance over the Gothic, and after that time the unity of the Spanish nation was maintained by the Catholic religion and the political influence of the clergy. But after retaining the mastery of the country for nearly

two centuries the Visigoths were in their turn conquered by the Arabs or Moors of Africa, who had come across at the invitation of the family of Alaric, the latter being eager to avenge themselves on their countrymen for being passed over in the election of king. King Roderic fell in the seven days' battle against Tarik at Xeres de la Frontera, in Andalusia, in 711. After that the greatest part of Spain became a province of the caliphs of Bagdad.

For some years after their conquest of Spain the Moors held it as a dependency of the province of North Africa; but it was afterward (717) governed by emirs appointed by the caliphs of Damascus. The policy of the Spanish emirs was to extend the Moorish dominion beyond the Pyrenees into Gaul, and the 40 years of their rule was marked by much bloodshed and anarchy, consequent on their disregard of internal affairs. About the year 756 Abd er Rhaman I, the last caliph of the dynasty of the Omniades, having been driven from Damascus, where he was replaced by the Abassides, succeeded in overthrowing the government of the latter in Spain and established the independent caliphate of Cordova, which under Abd er Rhaman III and his son Hakkem II, who died in 976, reached its zenith of power and prosperity. After the deposition of Hescham III the caliphate rapidly declined, for when that event took place the various governors of provinces declared themselves independent and assumed the title of kings. Thus Arabian princes reigned at Saragossa, Toledo, Valencia and Seville, where not only the language but also the manners of the Moors at that time prevailed almost universally. Still the free exercise of their religion was allowed to the Christians, and also the retention of their language, laws and magistrates.

Meantime the Visigoths, who had succeeded in maintaining their independence in the mountains of Asturia and Galicia, founded under Pelayo in 718 the kingdom of Oviedo. The second successor of Pelayo, Alfonso I the Catholic, conquered Galicia, with a part of Leon and Castile, and assumed the title of king of the Asturias. The remainder of Leon was conquered by Alfonso III, whose son, Ordoño II, transferred his residence to the city of Leon, and called his dominion the kingdom of Leon (914). The kingdom of Navarre came into existence in the 9th century. It formed a part of the Spanish territory of Charlemagne, obtained by conquest from the Arabs, and extending south of the Pyrenees as far as the Ebro. Near the sources of the Ebro and Pisuarga arose even earlier the kingdom of Castile. At first a small republic, consisting of only a few towns, it appears afterward as a country with a considerably enlarged territory, and somewhat later its princes assumed the title of king. In 1037, after the death of the last king of Leon, Ferdinand I of Castile united that kingdom with his own and Castile was henceforth the most powerful Spanish state. Aragon, Galicia, Portugal, Murcia and other states owed their origin to the prevailing custom of dividing a kingdom among the sons of a deceased monarch. Though frequently at war with each other the Christian princes generally united against their common foe, the Moors, who were daily becoming less able to cope with them. About the end of the 11th century Mohammed of Cordova and Seville applied for assistance against

Alfonso VI of Leon and Castile to the Almoravides, the founders of the empire of Morocco. In compliance with the request of Mohammed the Almoravides entered Spain and gained some successes over Alfonso; but they then turned upon Mohammed himself, obliging him to yield them a portion of his territory, and the Almoravide sovereign was ultimately acknowledged sole monarch of Mohammedan Spain. The Almoravides, however, were overpowered in their turn by another Mohammedan tribe, the Almohades, about the middle of the 12th century. Meanwhile the Christian kings were making still further encroachments on the territory in possession of the Mohammedans, and after the great victory they obtained over the Almohades on the plains of Tolosa, in the Sierra Morena, in 1212, there remained to the Arabians only the kingdoms of Cordova and Granada, and even these were soon afterward obliged to recognize the supremacy of Castile. The two most important Christian states of Spain were Aragon and Castile, and they ultimately absorbed all the others. Aragon, which had been wrested from the Moors by Sancho III and left as an independent kingdom to his son Ramiro, fell by inheritance in 1131 to the counts of Catalonia and was afterward greatly enlarged under successive kings. Jayme I wrested from the Moslems the island of Majorca in 1229, and the whole of the kingdom of Valencia in 1239. Pedro III married Constance of Sicily, and notwithstanding the opposition of the Pope took possession of that island after the massacre of Sicilian Vespers (see SICILIAN VESPER) in 1282. Jayme II effected the conquest of Sardinia in 1326, and Alfonso V united Naples with his kingdom. Meanwhile the internal affairs of the kingdom had been thrown into confusion through civil dissension resulting from the heavy imposts laid upon the people; but a remedy was found in increasing the power of the Cortes. Aragon was the first Christian state in which the third estate obtained a legal position. The Cortes, consisting of representatives of the nobility, of the clergy and of the towns, received more extensive privileges, and the king could not act in important matters without their consent. On the extinction of the Catalanian line of princes, Ferdinand, infante of Castile, was elected king by the Cortes in 1412, and his descendants ruled over Aragon until, through the marriage of Ferdinand V of Aragon with Isabella of Castile, Christian Spain was consolidated into one kingdom. Ferdinand I, second son of Sancho, was the first king of Castile in 1033, and as already mentioned joined the kingdom of Leon to the crown of Castile. He waged successful war with the Moors, took several towns and exacted tribute from the Mohammedan king of Toledo. It is to this reign that the greater number of the exploits of the famous Rodriguez Diaz de Bivar, known under the name of Cid, belongs; and according to Viardot the establishment of the Cortes dates from the same reign. Under Alfonso VI Castile acquired an accession of importance through the annexation to it of the crowns of Leon (which had become again disunited), Galicia and Navarre, and above all through the conquest of Toledo and its territory, out of which was formed New Castile. Notwithstanding the success of its arms the country suffered much. Oppressed by taxes and desolated by war it was

far from being in a prosperous condition. Under Ferdinand III, who ascended the throne in 1217, Cordova, Jaen, Alcala, Seville, Cadiz and other places were wrested from the infidels; and again under his successor, Alfonso X (1252-80), further conquests were made, though some losses were also sustained. To the latter prince is due the introduction of the third estate into the national assemblies, and the adoption of the vernacular for public acts. Alfonso XI (1324-50), like his predecessors, spent most of his time in warring with the Moors; he gained in 1340 the celebrated battle of Salados and made himself master of Algesiras in 1344. In 1465 Henry IV was deposed by his turbulent vassals and the crown given to Isabella, whose marriage with Ferdinand of Aragon in 1469 led to such important results. The marriage of these two sovereigns did not lead immediately to a complete coalescence of the two kingdoms, for they retained the separate administration of their respective dominions. But in concert with their great minister, Cardinal Ximenes, they proceeded harmoniously with the work of fusing all the states of Spain, which still differed in religion, customs and laws, into a political and ecclesiastical unity, at the same time seeking to strengthen the royal authority at the expense of the clergy, the aristocracy and the towns. By a severe administration of justice, and by the institution of the Santa Hermandad, or Holy Brotherhood—a body of about 2,000 police armed and mounted for the purpose not only of putting down the robberies and violence which everywhere abounded, but also of forming a check on the power of the nobility—order was established throughout the country. The royal power was moreover strengthened and extended by the establishment of the Inquisition (q.v.). Warfare also was carried on by Ferdinand against the Moors of Granada, which, undertaken in 1481, culminated 10 years later in the reduction of the capital of that kingdom, which surrendered to Ferdinand 25 Nov. 1491. With the fall of Granada fell the Moslem empire in Spain, after having existed nearly seven centuries and a half, and Spain, with the exception of Navarre, was now consolidated into one great kingdom. An order was issued, 30 March 1492, for the expulsion of all Jews who did not submit to be baptized, whereupon nearly the whole race, rather than sacrifice their religion to their worldly interests, left the country. In this sentence of banishment the Moors were also included and the departure of the industrious Jews and Moors proved a fatal blow to the flourishing commerce of the country, which was further affected by the discovery of America by Columbus in 1492, this being the means of withdrawing much of the activity of the nation from the improvement of the mother-country. While Spain consummated its complete political consolidation at home by the conquest of Navarre, the conquest of Naples by Gonsalvo, and still more the occupation of large portions of North, Central and South America by Spanish generals, soon raised the new kingdom to the front rank of European powers. Ferdinand was succeeded in 1516 by his grandson, Charles I (Charles V of Germany), who permanently united Castile and Aragon. (See CHARLES V) At the beginning of his reign serious insurrections broke out in Valencia and Castile, where the people

demanding a more liberal constitution; but they were soon quelled and resulted in the abolition of the principal rights of the towns, the restriction of the powers of the Cortes and a stronger attachment of the clergy and nobility to the Crown. The victory of the Spaniards at Pavia 24 Feb. 1525, which made Francis I the prisoner of Charles, and the expedition against Tunis and Algiers, extended the fame of the Spanish arms throughout Europe. But these wars together with those carried on against the Protestants of Germany, against the people of Ghent in the Netherlands and against Pope Clement VII in Italy, exhausted the revenues of the country. The immense wealth that flowed in from Mexico, conquered by Cortes in 1518, and from Peru and Chile, conquered by Pizarro and Almagro in 1531, was not sufficient to supply the demands of the royal treasury, and though the taxes were largely increased a heavy debt had to be contracted. With the reign of Philip II (1556-98), the son of Charles, the great monarchy began to decline. Oppression and religious intolerance, war and insurrections, occasioned the loss of the Netherlands and depopulated the rest of the monarchy; and the conquest of Portugal, which remained united with Spain from 1581 to 1640, could not prevent its decay. England and Holland triumphed over the naval force of Spain and destroyed her commerce; and Philip died in 1598 a bankrupt. This calamitous period was nevertheless the golden age of literature and art in Spain and the Spanish language and fashions controlled the courts of Europe. Under the reign of the indolent and incapable Philip III (1598-1621) the country took still greater strides toward decay. The Duke of Lerma, his insatiable favorite, in order to augment his own fortune and that of his partisans, squandered in a most scandalous manner the public revenues; and he struck another blow at the commerce of the country by expelling, in 1609, the last remnants of the Moriscos, to the number of 600,000. Equally damaging to the interests of the country was the reign of Philip IV (1621-65), notwithstanding some energetic measures taken by Olivarez, the able minister of that monarch. The wars which were carried on in Germany, Italy, the Netherlands and France—the war with the last-named country ending in the loss to Spain of Roussillon—helped to complete the ruin of the country and stirred up revolts in Catalonia, Andalusia and Portugal. The civil war in Catalonia lasted about 10 years and in 1640 Portugal recovered her independence. The son of Philip IV, Charles II (1665-1700), a prince weak alike in mind and body, was obliged, after disastrous wars, to cede to France many places in the Netherlands and Franche Comté. The population of Spain, which had amounted to 11,000,000 in 1688, fell off to about 8,000,000 at the beginning of the 18th century.

Charles II, the last Spanish sovereign of the race of Hapsburg, in his second will made Philip of Anjou, a grandson of his sister, the consort of Louis XIV, sole heir of his dominions, in order to prevent the division of the Spanish monarchy, which had been resolved on in a treaty between England, Holland and France. Louis XIV acknowledged his grandson king, according to the testament; but the Emperor Leopold I, of the race of Hapsburg, laid claim to the throne, while William III, king of Eng-

land and stadtholder of Holland, was in favor of a division of the monarchy for the sake of preserving the balance of power in Europe. The measures of Louis XIV at length brought on a war with England. Thus began the War of the Spanish Succession, which lasted 12 years and in which the Bourbon, Philip V, after many changes of fortune, succeeded in maintaining himself, by the victories of Berwick and Vendôme, on the Spanish throne in opposition to Charles of Austria (afterward the Emperor Charles VI). But by the Peace of Utrecht in 1713 he was obliged to resign the Spanish dependencies in Europe — Naples, Sardinia, Parma, Milan and the Netherlands to Austria, and Sicily to Savoy. England likewise retained Gibraltar and Minorca, the later of which was restored somewhat later. Under the Bourbons the nation lost its last constitutional rights; Aragon, Catalonia and Valencia were treated by Philip as conquered countries. The last diet of the Cortes held in Castile was in 1713 and in Aragon in 1720. Biscay and Navarre alone retained some of their privileges. The ambition of Cardinal Alberoni involved Europe for a short time in confusion. Spain in 1735 again obtained possession of the Two Sicilies for the Infant Carlos and of Parma for the Infant Philip in 1748. Ferdinand VI (1746-59) succeeded his father, Philip, but being a prey to hypochondria took no active part in the government. With his stepbrother, Charles III (1759-88), previously king of Naples, an enlightened prince, better days dawned for Spain. Under his reign the Bourbon family compact of 1761 involved Spain to its injury in the war between the French and British. The expeditions against Algiers likewise miscarried, as did the siege of Gibraltar in the war of 1779-83. Yet this did not disturb the course of the internal administration to the improvement of which men like Aranda, Campomanes, Olavides and Florida Blanca devoted themselves. They provided particularly for the advancement of agriculture, the useful arts and commerce, and this had a beneficial effect on the population, which now rapidly increased. The progress in improvement became even more marked during the early part of the reign of Charles IV (1788-1808), who at first pursued the reforming policy of his father; but in 1792, when Florida Blanca was superseded by Godoy as Prime Minister, he fell under the pernicious influence of that favorite. Spain at first entered with zeal into the war against the French Republic; but by the influence of the favorite the discreditable Peace of Basel was concluded, by which Spain resigned Santo Domingo to France, an offensive and defensive alliance with France was entered on (1796) and war declared against Britain. In 1797 the Spanish fleet was defeated near Cape Saint Vincent, Minorca and Trinidad occupied by the English and all the ports of Spain blockaded. By the Peace of Amiens in 1802 the British were confirmed in their possession of Trinidad. In 1801, at the instigation of France, military operations were commenced against Portugal, which was obliged to cede the province of Olivença to Spain at the Peace of Badajoz in 1802, while France raised the Duke of Parma to the dignity of king of Etruria in 1801, Spain in return ceding Louisiana to France. Charles

IV, on the renewal of the war between Britain and France in 1803, having purchased permission to remain neutral by a monthly tribute of 6,000,000 francs to Napoleon, the British seized the Spanish galleons and thereby forced Spain to declare war against Britain. The victory of the British at Trafalgar, 21 Oct. 1805, destroyed its naval power. The misery occasioned by the unfortunate wars, carried on by Spain at this time led to the formation of a powerful party against the unscrupulous Godoy, who was mainly instrumental in bringing about these wars. Some feeble efforts were made by him to free Spain from French domination; but the success of Napoleon in his war with Prussia thwarted those and in terms of the alliance subsisting between Spain and France a requisition of Napoleon to dispatched two Spanish armies to Denmark and Tuscany, respectively, had to be complied with. Spain received a further humiliation by the Treaty of Fontainebleau respecting the division of Portugal, in consequence of which French troops were marched into the country. Toward the end of 1807 large bodies of French troops entered Spain at different points and occupied on one pretense or another some of the strongest fortresses in the north. The entrance of a French army 35,000 strong in March 1808 raised the numbers of French troops in the country to 100,000 and with Murat at their head they now marched on Madrid. Godoy, in despair of his life, counseled the flight of the king and queen to Mexico. The project got wind; the people broke into open insurrection and the reign not only of the favorite but of his master also was at an end. Charles IV abdicated in favor of his son, the Prince of Asturias, who ascended the throne as Ferdinand VII. Ferdinand made a public entry into Madrid, which had been occupied by Murat, Grand Duke of Berg, the day previous. He informed Napoleon of his assumption of the royal power; but the emperor caused the whole family to be conveyed to Bayonne. Charles IV, who had retracted his resignation of the crown, and Ferdinand VII, the new king, were now both in the hands of Napoleon. Taking advantage, therefore, of the opportunity, he extorted from each of them, as well as from the Infantes Don Carlos and Don Antonio, a resignation of their claims to the Spanish crown. The crown, which had already been refused by his brother Louis, king of Holland, was now offered to another brother, Joseph, the king of Naples, by whom it was accepted. The Council of Castile, the chief political body of Spain, when informed of the treaties of Bayonne, was at length induced to give a reluctant assent to the accession of Joseph. A junta of 150 Spanish notables which had been summoned to Bayonne accepted a constitution proposed by Napoleon for Madrid. The Spanish people, who were so little taken into account in these changes, were by no means passive spectators of them. Insurrections had already broken out immediately after the abdication of Charles in May. The people in Asturias first took up arms; Aragon, Seville and Badajoz followed. Palafox carried from Bayonne to Saragossa the order of Ferdinand that the people should arm, and the supreme junta received permission to assemble the Cortes. Revolution broke out everywhere, which

the French were too weak to resist. Moncey retreated to Valencia, and Generals Dupont and Wedel were beaten at Baylen. The junta at Seville had issued a proclamation calling the people to arms and the Council of Castile decreed a levy of 300,000 men. The French squadron at Cadiz surrendered to the Spaniards and six days later an insurrection broke out in Portugal. On 4 July 1808, the alliance of Great Britain with the Spanish nation was proclaimed and a struggle began, which, whatever opinion may be entertained respecting the conduct of Napoleon, everyone will admit to have brought with it, as far as respected Spain, little but evil. Marshal Bessières was successful in the battle at Medina del Rio Secco, over General Cuesta; but the affair at Baylen above mentioned decided the retreat of the French from Madrid, and, 23 August Castanos entered the city. In the meantime Sir Arthur Wellesley (Wellington) had disembarked in Portugal at the head of the British forces and on 21 August gained the first important battle in the Peninsular war, defeating the French under Junot at Vimeiro. On 30 August the convention of Cintra was concluded, by which the French agreed to evacuate Portugal. A central junta under Florida Blanca was organized at Aranjuez toward the end of September; but unity did not prevail in it and the favorable moment was allowed to escape. On 6 November Napoleon reached the Ebro at the head of a large force and by a succession of victories gained by his generals under his direction his way was opened to Madrid, which he entered on 4 December. The central junta now retired to Badajoz and afterward to Seville. The Spaniards believed that the success of the French was owing to treachery and this suspicion occasioned the assassination of more than one of their generals. The French indeed gained many victories and took many fortresses; but the conquerors remained masters only of the places which they occupied. Everywhere the invading troops were surrounded and harassed by the attacks of the Spanish guerrillas. No line of communication was safe for the French; their means of support failed. In vain did Napoleon, 4 Dec. 1808, abolish the feudal privileges and the Inquisition; in vain did Joseph try every means to win the love of the people; nothing could avail against the hatred of a Gallic yoke. Austria now declared war and Napoleon was obliged in January 1809 to leave the conduct of the war in the Peninsula to his marshals—a step which the Spaniards considered as equal to a victory. During the following five years the French generals did all that talent and courage could do; but the charm of Napoleon's presence was wanting and Wellington finally triumphed over them. See PENINSULAR WAR.

After Pampeluna had fallen, 31 Oct. 1813, no French soldier was left on the Spanish territory except in Barcelona and some other places in Catalonia. Wellington attacked the enemy on the fortified banks of the Nivelle 10 November and Soult retreated into the camp of Bayonne. On 26 Feb. 1814 Wellington fought a battle with Soult at Orthez, by which the latter was driven from his strong position and obliged to retreat in great disorder to the upper Garonne. Wellington followed the

French under Soult to Toulouse, where the bloody battle of 10 April and the occupation of the place put an end to the war.

The Cortes had already held its first session and had resolved that Ferdinand VII should swear to preserve the constitution before he should be recognized as king. At their invitation Ferdinand now returned to Spain, but declared the constitution null and void; the Inquisition was revived, despotism was restored and the greater part of the reforms introduced under Charles III were subsequently annulled. Ferdinand bore down all opposition with a high hand and for six years (1814-20) reigned with absolute power. From 1814 to 1819 there were 25 changes in the ministry, mostly sudden and attended with severities. They were produced by the influence of the *camarilla* or persons in the personal service of the king. Every attempt to save the state was frustrated by such counsellors and the prestige of Spain was further lowered by the loss of the American colonies, an attempt to reconquer which only resulted in a miserable failure. On 1 Jan. 1820, a military insurrection under Riego broke out, for the purpose of restoring the constitution of 1812. It spread with great rapidity; several generals, as O'Donnell and Freyre, who were dispatched to suppress it, joined the insurgents and Ferdinand, abandoned by his own troops, was obliged to swear to observe the constitution of 1812. Among other reforms the Inquisition was abolished. The Cortes being assembled immediately set themselves to frame such measures as should be calculated to restore tranquillity to the distracted country. But this was a task well nigh impossible under the circumstances. The country was divided into opposing factions—those who favored the restoration of its ancient power and privileges to the Crown and those, on the other hand, who advocated liberal or ultra-liberal measures, and the measures passed had no effect in allaying the discontent. Guerrilla bands were organized in the provinces in the cause of Church and king and obtained the name of "armies of the faith." There was even established at Seo d'Urgel in July 1822 what was called "a regency during the captivity of the king." The government, however, was powerful enough to disperse these guerrilla hands and drive the regency into France. In these civil disturbances dreadful atrocities were committed on both sides. In the meantime France, at the Congress of Verona in October 1822, had agreed with the courts of eastern Europe upon an armed intervention in Spain. The Spanish government was called upon to restore the royal sovereignty and to change the constitution, and when they declined to comply a French army 100,000 strong, under the Duke of Angoulême, crossed the Pyrenees in the spring of 1823. By means of this force Ferdinand was restored to absolute power and immediately revoked all the decrees passed by the constitutional government between March 1820 and October 1823. The Inquisition, indeed, was not restored; but the secular tribunals supplied its place and performed deeds of vengeance of the most atrocious description. The whole Spanish army was now disbanded and its place supplied by the "army of the faith," who plundered and murdered the constitutionalists to their hearts' content. It is

computed that 40,000 constitutionalists, chiefly of the educated classes, were thrown into prison. To restrain the violence of party fury a treaty had been concluded with France, stipulating for the maintenance of a French force of 45,000 men in the country, until the Spanish army could be organized. It was only in 1827 that the French evacuated Spain. The personal moderation of the king toward the constitutionalists led to the formation of a plot by the absolutists to compel him to abdicate and to raise Don Carlos, his brother, to the throne (thence their name of *Carlistas*). Several insurrections were set on foot by these Carlists, which were attended with numerous executions. In 1830 Ferdinand was persuaded by his wife, Maria Christina, a Neapolitan princess, to abolish, by the pragmatic sanction of 29 March, the Salic Law of the Bourbon family, which excluded the daughters of the king from the throne. In consequence of the abolition of this law the succession passed from Don Carlos to Ferdinand's daughter, the Infanta Isabel. Don Carlos and his party protested against this measure, and the death of Ferdinand in 1833 was the signal for civil war. Isabella was at once acknowledged by the leading powers of Europe and proclaimed without opposition in all the midland and southern provinces of Spain. It was otherwise in the north, particularly in the Basque province; there the inhabitants took up arms in behalf of Don Carlos and proclaimed him king, under the title of Charles V. Christina had the joint support of the moderados and the liberals and in order to attach them to her still more, a royal decree was issued in April 1834 granting a constitution with two chambers. The Carlists, under the command of Zumalacarregey, were at first successful, but on his death their cause began to decline and the skilful leadership of Cabrera failed to retrieve the fortunes of the party. During this struggle England and France allowed men to be recruited within their territories for the cause of the queen and an army of 10,000 went from England to join the royal troops. The chief of the royalist generals were Espartero and O'Donnell, under whose leadership the war was brought to an end in 1840. Though the civil war had thus been brought to a successful termination, Spain had by no means been restored to a state of tranquillity. Christina failed to satisfy the ultra-liberals and rather than consent to have a colleague in the regency, as it was now thought expedient she should have, resigned 12 Oct. 1840, and sailed for France. In May 1841 the Cortes conferred the office of regent on Espartero and that of guardian to the queen on Arguelles. Espartero seems to have had the good of his country at heart, but he had a most difficult rôle to play. Every reform which he attempted gave offense to some party and to whatever side he turned he met only with opponents numerous, resolute and influential. Insurrections broke out in various quarters, and Espartero, checked and hampered on all hands, at last left the country and sailed for England. Queen Isabella was declared of age by the Cortes in 1843 and henceforth the government was carried on in her name. She was married on 10 Oct. 1845 to her cousin, Don Francisco d'Assiz, her only sister, Louisa, being on the same day married to Louis

Philippe's son, the Duke of Montpensier. The outbreak of the French Revolution of 1848 caused much less commotion in Spain than in several other Continental states. Any revolutionary movements that took place were easily repressed by Narvaez, a minister of prudence and energy, who was then at the head of the government. Narvaez, however, found no small difficulty in maintaining his position. The court was a mere focus of intrigue and the most important political changes were constantly threatened to be effected by the most frivolous and contemptible means. Early in 1851 he was compelled to resign, and till 1854 a number of short-lived and weak ministries, most of which had reactionary tendencies, succeeded each other. At the head of the last of them was Sartorius, whose measures were so unpopular that insurrection broke out in various quarters, and he and his colleagues, after trying in vain to suppress them, were obliged to save themselves by flight on the 17th of July 1854. Espartero, who had some time before returned to Spain, was now charged with the formation of a government in accordance with the wishes of the nation. Before consenting to undertake this task he made two stipulations—the one that the queen-mother should be exiled, the other that the constituent Cortes should be assembled. On obtaining these concessions he formed a coalition ministry, himself holding the office of President and General O'Donnell that of Minister of War. The coalition ministry did not, however, work harmoniously, and Espartero, after holding his position with some difficulty till 14 July 1856, was obliged to give place to another ministry, with O'Donnell at its head, which only existed three months. Narvaez was now called to the head of affairs (October 1856). But in July 1858, O'Donnell was again entrusted with the formation of a ministry, which, being more liberal than the previous ones, endured for a period of five years, during which Spain enjoyed comparative tranquillity. In 1858 Spain shared in the French expedition against Anam, to avenge the persecution of Catholic missionaries and native Christians, which had been going on for a series of years. On 22 Oct. 1859, war was declared against Morocco, which, it was alleged, had attacked the Spanish possessions situated on the northern coast of that state. Under the leadership of O'Donnell it was carried to a successful conclusion and a treaty of peace was signed on 26 April 1860, in terms of which 20,000,000 piastres were paid to the Spaniards by way of indemnification. These foreign wars led to a considerable increase of the army and navy, promoted peace at home and greatly raised the reputation and influence of Spain abroad. In 1860 an unsuccessful attempt was made to overthrow the government of Isabella by the Count of Montemolin, the eldest son of Don Carlos, in whose favor the latter had in 1845 abandoned his claim to the Spanish throne. In 1861 Spain joined Britain and France in sending an expedition to Mexico to obtain redress of grievances. The same year Spain resumed possession of her former colony of Santo Domingo. On 18 March the last President of that republic, Santana, issued a proclamation announcing the union of that state with Spain, and on 20 May the queen signed the decree by which the an-

nexation was accepted. In 1863, however, a revolt broke out and after some fighting, which continued into the following year, Spain relinquished the possession once more. A quarrel at this time broke out between Spain and Peru, in consequence of which the Spaniards seized the Chinchá Islands by way of material guarantee; but in the early part of 1865 the differences between the two governments were adjusted and the Chinchá Islands restored to the Peruvian authorities. A more serious rupture took place in the same year with Chile, which led to a war between the two countries. The Chileans were supported by Peru, Ecuador and Bolivia; but Spain had not very much to fear from this combination, though at the same time, as might have been expected, the war procured her little either of honor or profit. A military insurrection broke out in Spain toward the end of 1865, under the leadership of General Prim, but he and his adherents were forced to flee before the royal troops. Prim effected his escape to Portugal, but in the following year another attempt at insurrection was made. On 22 June a regiment of artillery, quartered in Madrid, mutinied in their barracks, and after murdering several of their officers marched through the streets of the city calling upon the people to rise in the name of "Prim and the republic." The active measures, however, of the Prime Minister, Marshal O'Donnell, soon put down the revolt. An equally abortive rising, though on a larger scale, took place in August 1867 in Aragon, Catalonia, Valencia and elsewhere, where bands of armed men made their appearance, and were in some instances joined by the mayors of towns and other functionaries. The movement in a short time wholly collapsed, and several persons engaged in it were taken prisoners and executed. But the Revolution of 1868 had a very different issue. The conduct of the queen had alienated all feelings of loyalty in the breasts of her subjects. The forms of the constitution had been abused, and made the machinery of arbitrary and oppressive rule, and the people were weary of a system which repressed all freedom of thought and rights of conscience, which placed the education of the young in the hands of Jesuits, and under which they had lost all respect for their ministers and all attachment to the Crown. In the month of April insurrectionary movements broke out in Catalonia, and the province was placed in a state of siege. In July several Spanish generals were arrested by the government, and without any form of trial sent into exile. The revolution burst forth in September. On the 17th of that month General Prim arrived at Cadiz, where the exiled generals also arrived two days later, and immediately lent themselves to the movement. Meanwhile a proclamation had been issued calling the people to arms. Marshal Serrano, formerly president of the Senate, placed himself at the head of the movement and the whole of Andalusia pronounced for the revolution. The Spanish ministry resigned, and General Concha was appointed by the queen president of the council. The Marquis de Novaliches commanded the royal army, and marched upon Cordova, which was occupied by the insurgents. At Burgos a severe conflict took place, which resulted in the royal troops fraternizing with the people. Juntas were established in the dif-

ferent towns, which one after another raised the flag of rebellion. The defeat of Novaliches at Puerta Alcañen and the formation of a provisional junta at Madrid determined Isabella to flee the country and take refuge in France. Immediately after her flight the fall of the Bourbons was solemnly proclaimed, and one of the first acts of the juntas was to recognize universal suffrage as a principle of the future constitution. Serrano entered Madrid at the head of the revolutionary troops on 3 October and was received with the utmost enthusiasm by the inhabitants. A few days later a provisional ministry was formed, "to lead the nation to liberty, and not allow it to perish in anarchy." Decrees were passed suppressing the Society of the Jesuits, declaring the absolute freedom of primary education, and restoring the liberty of the press. Thus was accomplished with little violence and less bloodshed a revolution which marks one of the most important eras in Spanish history. The Cortes of 1868 declared for the monarchical form of government; but it was no easy task to find a prince both able and willing to fill the hazardous post of king. After fruitless negotiations with several princes, which, in the case of one of them, the Prince of Hohenzollern, led indirectly to the disastrous Franco-German War (q.v.) of 1870, the Crown was at length accepted by Amadeus, the second son of Victor Emmanuel, and on 16 Nov. 1870, he was formally elected as king by the Cortes. Meanwhile insurrectionary movements in several of the provinces had disturbed the peace of the country, but were forcibly suppressed. The new constitution was promulgated 6 June 1869, and Serrano appointed regent until a king was elected. The two years' reign of Amadeus I failed to give peace to the much disturbed country. Parties were numerous and irreconcilable. One ministry had to give place to another, each successive change making matters worse instead of better. To crown all, in April 1872, the Carlist insurrection, which had been for some time threatening, burst forth. Risings took place simultaneously, under old chiefs of the party, in Aragon, Navarre and the Basque provinces; and bands also rapidly formed in Leon, Castile, and elsewhere. The cry of "Viva Carlos VII" was heard on all sides. No time was lost by the government in dispatching Marshal Serrano to the scene of action. He succeeded in driving the insurgents before him, and coming up with the main body on 4 May at Oroquieta defeated them. The check they received was, however, only temporary, as they still kept up a species of guerrilla warfare, and the year 1872 closed amidst widespread confusion in the provinces, and excitement in the capital itself. "The Carlists in the north, the federalists in the south, overran the country, exacting contributions, cutting the railways and telegraph wires, inflicting heavy damages upon the state and on private families, putting a stop to all commercial intercourse, undermining local trade, protecting and facilitating smuggling, and obtaining unlimited authority wherever they went"; and in this state of disorganization the country continued long after all active fighting had ceased. Disaffection in the army added to the strife of parties, and the many opposing manifestations of public opinion at length de-

terminated the king to resign a crown the wearing of which had caused him nothing but anxiety and unrest. He accordingly abdicated on 11 Feb. 1873; and immediately thereupon the Cortes, by a majority of votes, declared for a republic, which was officially proclaimed at Madrid on 16 February. This was followed by political complications of the most chaotic description, a state of affairs which the Carlists were not slow in taking advantage of. Not only, however, were the Carlists active, but other insurrectionary movements, consequent on the general discontent, combined to complicate the difficulties of the government. On 8 June the form of government, which had been the subject of much dispute, was, by an almost unanimous vote of the Cortes, definitely declared to be that of a federal republic. The Ministers under it were as short-lived as previously. On 21 September Castelar, who at that time was President, was invested with dictatorial powers by a resolution of the Cortes, who voted their own suspension till 3 Jan. 1874. At the expiration of that period matters were in no way improved. Public opinion was wholly disorganized, and the Carlist war had gained formidable dimensions. January 3 saw another revolution of government; the Cortes had re-assembled, and on a motion being made for the approval of Castelar's exercise of authority during the recess it was negatived by a large majority. Castelar at once presented the resignation of himself and cabinet. As soon as this event was known out of doors, General Pavia, the captain-general of Madrid, at the head of his troops, entered the chamber and forcibly dissolved the Cortes; and having assembled the chiefs of the Revolution of 1868, and leading men of all political parties, justified his conduct by the urgency of the case, and desired them to form a new coalition ministry. The parties now placed in power, with Serrano at their head, were the same with those who made the Revolution of 1868 and the constitution of 1869. During this new revolution Madrid remained tranquil; but in Saragossa, Barcelona and Valencia volunteers were arrayed by the communal authorities against the troops of the government, and barricades were raised. The struggle, however, was of short duration, and soon quelled. Within 10 days after the inauguration of the new government a striking military success, in the capture of Carthage from the disaffected, came to give it credit. In the north the Carlist War still raged, and became more and more formidable. Bilbao made a stubborn resistance to the government troops, but ultimately fell, and this success was followed by a few others; but at the battle of Estella, fought on 27 June, the Carlists obtained a signal victory over the republicans, who lost nearly 5,000 men in killed, wounded and prisoners. The Carlists now overran the northeastern provinces, the fortresses only holding out against them. On 15 July, after a terrible bombardment, Cuenca fell into their hands. By the beginning of September the pretender's troops had entered several towns in different parts of Spain, though they had been, for the most part, unable to retain their acquisitions. The tide of success, however, again turned against the Carlists. They met with a signal defeat near Pampeluna on 25 September and

again at Irun on 11 November; but the republicans failed to follow up their successes or act as if they had any desire to bring the war to a speedy conclusion. Meanwhile another political change was in contemplation. The Alfonsists, or advocates of the Prince of Asturias, son of the ex-queen, consisting of a large majority of the middle and upper class of society, had been working steadily in his interests. On the prince's 17th birthday addresses had been presented to him at Sandhurst, in England, where he was pursuing his military studies as cadet; and on the last day of the year it was announced that Gen. Martinez Campos, proclaiming Prince Alfonso as king, had entered Valencia with two brigades. On the same day he was proclaimed in Madrid under the title of Alfonso XII. On 9 June 1875, the new king landed at Barcelona and assumed the government of Spain. The Carlist rebellion dragged itself on for more than a year after this event, but with fainter and fainter hopes of success. On 22 Feb. 1876, five battalions of Carlists surrendered at Tolosa to General Campos, and four days later Don Carlos fled to France. On 20 March following the young king made a triumphal entry into Madrid. Spain enjoyed a time of peace until his death in his 29th year, November 1885. His wife, Christina of Austria, was proclaimed regent after the birth in 1886 of her posthumous son, who is now king under the title of Alfonso XIII. Besides her struggles with the Carlists and others at home, Spain had to contend from 1868 to 1878, and again from 1895 onward, against insurgents in Cuba, where rebellion seemed almost the normal state of affairs. The United States intervened in 1898, and war ensued, resulting in the defeat of Spain, the almost complete destruction of her navy and the loss of her American and Asiatic colonies. (See UNITED STATES, WAR WITH SPAIN). The loss of the protected colonial markets greatly dislocated manufacturing interests, particularly in Catalonia, where the old separatist tendency is still strong. The year 1901 was marked by serious anti-clerical disturbances and the Sagasta government took a firm stand against the religious orders. The regency was terminated 17 May 1902 when Alphonse XIII came of age. In May 1906 the king married Princess Ena of Battenberg. In the same year the government sought to establish civil marriage and to regulate monastic establishments. Spain secured a rapprochement with France in 1904 by coming to an understanding with the latter in regard to Morocco; in 1908 both nations handled the Moroccan question in amity. The years 1908-09 were marked by anarchistic activities; a revolution was initiated at Barcelona which was soon suppressed and its leader, Francisco Ferrer, executed. In 1910-12 many internal reforms were instituted and Spain's relations with the Vatican placed on a more explicit basis. A measure of religious liberty to denominations other than Catholics was also enacted. Spain succeeded in maintaining her neutrality throughout the World War of 1914-18, although the feeling in Spain was sharply divided. The aristocracy and wealthy classes and a militaristic group sided with the Central powers, while the intellectuals and the great majority of the population took the part of France and the Entente. The Carlists

were pro-German and the Republicans pro-Ally. Maura was against neutrality and publicly stated that Spain's interests would be best served by joining the Entente. This stirred the German element to action and a counter-campaign was instituted. The government's position was rendered most difficult. The Romanones ministry fell early in 1917 and was succeeded by the Prieto ministry which lasted until 9 June 1917, when its fall was brought about by a crisis in the army, where a revolutionary movement developed. The Dato ministry partially succeeded in settling many of the points at issue and several reforms were instituted in the mode of army appointments, promotions, etc. The radical element demanded Parliamentary reform but met with little success. Strikes and disturbance, became very numerous throughout the country in June and July 1917 and on 13 August it was announced that the government had decided to declare martial law throughout Spain. Garcia Prieto succeeded Dato as Premier on 3 Nov. 1917 and formed a compromise ministry from several factions in the Cortes. It lasted only a short time, having failed to allay the general dissatisfaction. A new Cortes met on 18 March and a new ministry under Maura was formed. It lasted until 9 Nov. 1918 when Romanones was asked to form a new cabinet. Within eight weeks Prieto was again at the head of affairs and Romanones was Foreign Minister. Great dissatisfaction was manifested with the attitude of the government toward Germany's submarine warfare; disorder was rife in the industrial regions of the kingdom. The Prieto ministry fell from power on 3 Dec. 1918.

MARION WILCOX,
J. B. McDONNELL.

SPAIN, American Diplomatic Relations with. American relations with Spain, which have never been really cordial were largely influenced in the beginning by inherited traditions of Anglo-Spanish wars of two centuries.

In the Revolution, Spain withheld from alliance with the United States and in negotiations for peace planned to restrict the United States to territory east of the Appalachians. After 1783 she still hoped to obtain control of the trans-Appalachian west by restrictions on American commerce on the lower Mississippi and disputed with the United States the northern boundary of Florida concerning which the United States had a separate understanding with Great Britain. In 1795, however, she was induced to grant a deposit of American commerce at New Orleans and to recognize the American contention by agreeing to the northern Florida boundary at 31°.

In the two decades closing in 1815 Spain acted with France in the spoliation of American shipping, especially in the West Indies, resulting in later American claims for compensation. Another source of irritation and diplomatic negotiation arose from the secret transfer of Louisiana to France in 1801 and the later acquisition from France by the United States in 1803. In 1802 Jefferson offered to guarantee to Spain her trans-Mississippi territory for a cession of the island of New Orleans. After 1803 he claimed West Florida to the Perdido as a part of Louisiana, and by 1806 established a customs district therein in the face of Spanish protests. In 1810 the American government, under Madison, took possession of all West Florida which had declared its independence, and later extended jurisdiction farther east into territory over which Spain was unable to preserve order or to perform her international obligations.

In 1814, during the War of 1812 Jackson temporarily occupied Pensacola after driving out a British force which had occupied the place without the consent of the Spanish authorities. Later, in 1818, he again ignored Spanish sovereignty in this region by a defensive invasion which doubtless hastened the completion of negotiations which resulted in a treaty of 1819 (ratified 22 Feb. 1821) providing for acquisition of Florida by the United States and limits to Spanish western territory by a boundary established from the Sabine northward to the Red, up the Red to 100° longitude, thence north to the Arkansas and up the Arkansas to its head, thence north to 42° and thence west to the Pacific.

Still another source of friction was the revolt of the Spanish American provinces begin-

ning in 1810, and resulting in a period of privateering in which American-built vessels illegally participated under the flags of the revolting governments. The American government recognized the revolted provinces as belligerents and sent special agents to report conditions, but maintained neutrality. Finally, in March 1822, after the ratification of the Florida treaty, it recognized the independence of four provinces (Mexico, Colombia, Buenos Aires and Chile) and in 1823 issued the Monroe Doctrine to prevent attempts of European powers, acting under the Holy Alliance, to aid Spain in efforts at resubjugation. Later it recognized Central America and Peru and, partly through fear of international complications relating to Cuba and Porto Rico, continued to urge Spain, both directly and indirectly through other European powers, to enter into peaceful relations with the new-born republics.

Cuba, whose destiny appeared uncertain, became the chief subject of diplomatic relations thereafter. A plan of guarantee of Cuba to Spain by the United States and other powers, first suggested by the American Minister (Forsyth) at Madrid early in 1822 as a possible compensation for Spanish recognition of Mexico and Colombia and adoption of a liberal system of commerce, was considered both at Washington and London in 1823. For two decades after 1825 American policy practically guaranteed to Spain the possession of the island on condition that it should not be ceded to France or England. In 1840 and 1843 the American government officially assured Spain of the American policy to maintain Spanish occupation of Cuba by American military and naval force against any attempt to wrest the territory from her.

The failure of the new American policy to purchase Cuba by diplomatic negotiations in 1848 was followed by a period of unsuccessful filibustering attempts (aided by lawless, adventurous Americans) to encourage revolt in the islands, resulting in various complications and new international suspicions. Declining to accede to an Anglo-French proposal of 1851 for joint action to prevent the landing of filibustering adventurers in Cuba, and also refusing to become a party to the later proposal of 1852 for a tripartite agreement disclaiming any purpose to obtain possession of Cuba, the American government under the Pierce administration, through the influence of slavery interests, adopted a systematic policy of annexation, illustrated in 1854 by the incidents of the *Black Warrior* episode and the Ostend Manifesto (repudiated by Secretary Marcy) and finally terminated only by the new issues of the Civil War period.

In the American Civil War, relations with Spain were largely concerned with the question of Confederate plans or operations, affecting Cuban neutrality, in relation to the use of the island as a base for enterprises endangering the American Union, and the Spanish occupation of San Domingo which the American government disapproved and which ceased in 1865.

Relations again became strained through conditions affecting American interests in Cuba and consequent diplomatic difficulties resulting from the Cuban Revolution of 1868-78. In 1869 President Grant contemplated the recognition of the Cubans as belligerents, and even

avored intervention, but the American government limited its policy to presentation of complaints and demands and an offer of mediation to arrange a peace on a basis of Cuban independence. Relations reached a dangerous stage late in 1873 through American demands following the Spanish pursuit and capture of the *Virginius* on the high seas, and the execution of her captain and 53 of her crew at Santiago; but Spain finally yielded enough to secure an adjustment of the case. In November 1875 Secretary Fish, influenced by increasing difficulties which threatened to draw the United States into a war against Spain, confidentially sounded the chief European governments in regard to their views on a policy of foreign intervention in Cuban affairs.

After the pacification of Cuba in 1878, Spanish restrictive commercial regulations remained a continual source of complaint. The American government urged Spain to establish a more liberal government through independence or autonomy, to adopt a more liberal commercial policy and to secure better protection of American citizens and American property in Cuba. In 1884 and 1886 it obtained promises of the termination of discriminating and retaliatory duties, but the agreements were violated under various pretexts by the Cuban officials. In 1891 it was able to negotiate with Spain a reciprocity schedule under which American commerce was considerably increased in spite of the obstructions of Spanish officials in Cuba.

Three years later, the abrogation of this commercial arrangement injured the Cuban sugar industry and hastened the final devastating revolution of Cuba (in 1895), stimulated and aided by a Cuban junta in the United States and placing upon the American government a difficult problem of patrol to prevent filibustering while maintaining American rights. In 1896, embarrassed both by Cuban activities in the United States and Spanish treatment of American citizens in Cuba, the American government, under President Cleveland, made an offer of good offices for mediation which, however, was declined. It then gave warning that American forbearance has limits. In 1897, under President McKinley, it again used efforts to secure a peaceful solution of the difficulties.

Finally, after new sources of irritation culminating in the incident of the destruction of the *Maine* in Havana Harbor, it actively intervened in 1898 to terminate the intolerable conditions of Spanish rule in Cuba and to establish Cuban independence under an American protectorate. The resulting Spanish-American War was closed by peace negotiations through which Spain lost all her colonies in the West Indies and the Far East, and the United States obtained a stronger strategic position in the Gulf of Mexico and the Caribbean Sea besides the control of islands of the Pacific needed for coaling stations and suitable bases for exercise of a larger American influence in the Far East.

By treaty of 10 Dec. 1898, Spain relinquished sovereignty over Cuba, transferred Porto Rico and Guam as a result of conquest, and ceded the Philippines for \$20,000,000.

A new treaty of friendship and general relations was concluded in July 1902 (proclaimed 20 April 1903). An international copyright agreement of 1895 was restored by interchange

of notes 26 Nov. 1902, and an extradition treaty was concluded in June 1904 and (with a protocol of August 1917) proclaimed 21 May 1908. A commercial agreement for reciprocal tariff concessions, under the Tariff Act of 1897, was signed and exchanged in 1906, terminable in August 1910 by notice of the American government. An arbitration convention was concluded in April 1908, and extended by agreement of 1913. A new arbitration treaty was concluded in September 1914.

JAMES M. CALLAHAN,
Professor of History and Political Science,
West Virginia University.

SPALDING, Albert, American violinist: b. Chicago, 15 Aug. 1888. He studied under Jean Buitrago in New York, under Chiti at Florence and Lefort at Paris. He made his début at Paris in 1906 and achieved an immediate success. His later tours in France, Germany and England confirmed his reputation as an artist of signal ability. He made his American début in New York in 1908 and in the course of several seasons' work firmly established himself as a leading American violinist. He made many tours of the United States and Canada and also returned to Europe for a tour which extended through the leading European countries and into Egypt. In September 1917 he canceled his engagements for a concert tour of the United States and Canada in order to enter the United States Signal Corps, in which he received rank as lieutenant. Among his compositions are a set of variations for 'My Old Kentucky Home' and 'Concerto quasi fantasia' for piano and violin.

SPALDING, Albert Goodwill, American merchant, baseball player and official: b. Byron, Ill., 2 Sept. 1850; d. 9 Sept. 1915. As pitcher for the Boston Base Ball Club in 1871-75 he was one of the most famous base ball players of his day, his club retaining the championship for four successive seasons. In 1876-91 he was connected with the National Association Chicago Club, filling in turn the offices of manager, secretary and president. He also organized the National League. He was one of the founders in 1876 of the firm A. G. Spalding and Brothers, which became widely known as manufacturers of sporting goods. He lived at Point Loma, Cal., as a member of a theosophical colony from 1900 until his death. Author of 'America's National Game' (1911).

SPALDING, Frederick Putnam, American civil engineer: b. Wysox, Pa., 7 April 1857. He was graduated from the School of Civil Engineering of Lehigh University in 1880 and after practising for several years was instructor in the university, 1886-88; assistant professor of civil engineering at Cornell, 1891-98, and has held a similar professorship in the University of Missouri since 1900. His publications include 'Notes on Hydraulic Cement' (1893); 'Text Book on Roads and Pavements' (1894);

'Hydraulic Cement, Its Properties, Testing and Use' (1897).

SPALDING, John Franklin, American Protestant Episcopal bishop: b. Belgrade, Me., 25 Aug. 1828; d. Erie, Pa., 9 March 1902. He was graduated from Bowdoin College in 1853, from the General Theological Seminary, New York, in 1857, and was ordained to the priesthood in 1858. He had charge of various parishes in Maine and Rhode Island in 1859-62 and was rector of Saint Paul's Church, Erie, Pa., in 1862-73. In the year last named he was consecrated first bishop of the missionary diocese of Colorado. He was an able and forceful organizer and an active promoter of advancement in education. His publications include 'Modern Infidelity' (1862); 'The Higher Education of Women' (1886); 'The Church and its Apostolic Ministry' (1887); 'The Best Mode of Working a Parish' (1888); 'The Threefold Ministry of Christ' (1887); 'Jesus Christ the Proof of Christianity' (1891), etc.

SPALDING, John Lancaster, Catholic prelate: b. Lebanon, Ky., 2 June 1840; d. Peoria, Ill., 25 Aug. 1916. His preliminary studies were pursued at Saint Mary's, Kentucky, and subsequently he attended Mount Saint Mary's, Emmitsburg, and Mount Saint Mary's, Cincinnati, afterward entering the American College at Louvain, Belgium, and being there ordained to the priesthood in 1863. He then devoted a year to special studies in Rome, Italy, and having returned to America, was assigned to duty in the cathedral of Louisville, Ky. In 1866 he was accorded the honor of preaching at the Second Plenary Council of Baltimore, a rare privilege for one so young, and despite many obstacles, he founded in Louisville a parish for negroes. Requested to be the biographer of his illustrious uncle, Archbishop Spalding, who died in 1872, Father Spalding repaired to New York for the purpose, and upon completing his labor of love, became assistant to Father Donnelly at Saint Michael's Church, New York, where he soon established a reputation as a preacher of extraordinary ability, being called thence to the episcopal dignity and consecrated first bishop of Peoria, Ill., in Saint Patrick's Cathedral, New York, 1 May 1877. He was associated with Archbishop Ireland in founding the Catholic Colonization Society, and in him higher Catholic education has had one of its most ardent promoters. Long before the Catholic University at Washington assumed material proportions, it had been conceived in the mind of Bishop Spalding, who was tireless in planning for its foundation; and the elaborate Catholic educational exhibit at the World's Columbian Exposition in Chicago in 1893, of which he was president, was prepared largely at his instigation. President Roosevelt appointed him one of the board of arbitration for the settlement of the great anthracite coal strike in 1902. Columbia University conferred upon him the degree of LL.D., in June 1902. Bishop Spalding was twice stricken with paralysis and failing to recover full vigor resigned his charge 10 Sept. 1908. In 1909 he was made titular archbishop of Scythopolis. His writings are among the most scholarly contributions to American literature, 'Education and the Higher Life,' 'Things of the Mind,' 'Thoughts and Theories of Life and Education,' 'Opportunity and Other Essays,' 'Religion, Agnosticism and Education,' 'Socialism and Labor and Other Arguments' and 'Religion and Art, and Other Essays' (1905), being some of the most notable of his works. Bishop Spalding is also the author of poems.

SPALDING, Martin John, American Roman Catholic archbishop: b. near Lebanon, Ky., 23 May 1810; d. Baltimore, Md., 7 Feb. 1872. He was educated at Saint Joseph's College, Bardstown, Ky., and at Rome, Italy, where he was ordained priest in 1834. He received charge of the cathedral at Bardstown upon his return to America and was also professor of philosophy in the seminary. He was president of Saint Joseph's College, Bardstown, in 1838-40. In 1844 he was appointed vicar-general at Louisville; and in February 1848 he became coadjutor bishop, while on 10 Sept. 1848 he was consecrated bishop of Lengone *in partibus*. He founded the American College at Louvain in 1857, and was installed as archbishop of Baltimore in 1864. Author of 'Sketches of the Early Catholic Missions in Kentucky, 1787-1827' (1846); 'History of Protestant Reformation' (2 vols., 1860), etc.

SPALLANZANI, spāl-lān-dzā'nē, Lazzaro, Italian naturalist: b. Scandiano, 12 Jan. 1729; d. 12 Feb. 1799. He studied at Reggio and afterward at Bologna, under Laura Bassi, the celebrated woman professor of physics in that place. In 1754 he was appointed teacher of logic, metaphysics and Greek at Reggio. In 1760 he accepted a professorship at Modena and on the reconstruction of the University of Pavia, in 1768, he was appointed to the chair of natural history there and thenceforth devoted himself to experimental researches and published in Italian various works on physiology, which made his name known through Europe. Among the subjects which engaged his attention were the phenomena of generation, the functions of respiration, digestion and the circulation of the blood. In opposition to the opinion of Buffon and Needham, he proved that the Infusoria are really endowed with animal life and not merely organic molecules. Among his writings may be cited 'Experiments on Animal Reproduction' (1786); on 'Infusory Animals'; on the 'Phenomena of Circulation'; on 'Animal and Vegetable Physics' (1780); 'Transpiration of Plants.'

SPAN, a measure of length, being the distance between the tips of the thumb and little finger when the fingers are expanded to their fullest extent. This space averages about nine inches, which accordingly is the fixed measure given to the span. In architecture the term is applied to the width or opening of an arch.

SPAN-WORM. See MEASURING-WORM.

SPANDAU, spān'dow, Germany, in Prussia, a fortified town of Brandenburg, at the junction of the Spree and Havel, nine miles west-northwest of Berlin and now a suburb of that city. In the Julius tower of the citadel was deposited the reserve war fund of the empire—\$30,000,000. The basis of this sum was the French indemnity paid in 1871. Here are large foundries and factories for all firearms, guns and all munitions of war, also a garrison of several thousand men. The principal buildings are churches, schools—includ-

ing military schools for the different arms—artillery-construction bureau, factories for gunpowder, military and city hospital, etc. The fisheries and timber trade are important, also shipbuilding and horse and pigeon propagation for military purposes. The town was often the residence of the first electors of the house of Hohenzollern, and subsequently passed into Swedish hands—till 1634. In 1806 the French took possession and in 1813 was surrendered to the combined Prussian and Russian forces. Spandau is now the shipping centre for trade between Berlin and Hamburg. Pop. 84,855.

SPANDREL, or **SPANDRIL**, in architecture, an irregular space on a wall bounded by the outer curve of an arch and two lines meeting at right angles, the one drawn perpendicularly from the springing of the arch and the other horizontally from the apex, or by the outer curves of two contiguous arches and a horizontal line above them, or by similar curves of contiguous arches and the line of a larger arch enclosing the other two. This space, an approximate triangle, is excellent for decoration. It is sometimes decorated with figures in relief, as in the triumphal arches of Rome, or with medallions, as in many buildings of the Renaissance period. The term is also applied in engineering to the columns supporting the truss of a certain kind of steel-arched bridge, and also in the construction of a steel-skeleton building to the space between the top of a window and the sill of the next one above.

SPANGENBERG, späng'en-bërg, **Augustus Gottlieb**, German religionist: b. Klettenberg, Prussia, 15 July 1704; d. Berthelsdorf, Saxony, 18 Sept. 1792. He studied at Jena, abandoned law for theology, became a lecturer at the university and occasionally preached; in 1732 was made adjunct of the theological faculty at Halle and in 1733 was dismissed because of his doctrinal views. At once he entered the Moravian Church at Herrnhut and labored in Germany, America, the West Indies and England, where he established the Society for the Furtherance of the Gospel among the Heathen. After his consecration as bishop in 1744 he was at the head of the Moravian Church in America until his return to Europe in 1762. On his arrival in Germany he participated in framing the new constitution of the Church, of whose governing board he was the chief member. Among his works are 'Idea Fidei Fratrum' (1782; Eng. trans. by La Trobe, 'Exposition of Christian Doctrine,' 1784); and 'Leben des Grafen von Zinzendorf' (1775; abridged Eng. trans. by Jackson 1838). He also wrote some well-known hymns, such as 'Heil'ge Einfalt, Gnadenwunder' (Hymnal No. 432) and 'Die Kirche Christi, die Er geweiht' (Hymnal 612). Consult lives by Risler (1794); Ledderhose, K. F. (Heidelberg 1846; Eng. trans., London 1855); Knapp, G. C. (ed. by Otto Frick, Halle 1884), and Reichel, G. (Tübingen 1906).

SPANIEL, a small shaggy race of dogs, deriving its name from Spain, whence it originally came to Great Britain, and now generally divided into the two groups—sporting and toy spaniels. The common "field" spaniel is the type of the group and two breeds of this variety, "springer" and "cocker," are distinguished. The former is a heavy dog used for

beating game in thick coverts. The spaniel has the hair very long in some parts; it is generally white, with large brown, liver-colored or black spots, of irregular shape and size; the nose is sometimes cleft; the ears are very long and pendulous and covered with long hair. The tail is feathery and waves from side to side when the dog runs. Two famous breeds of springer spaniels are the black Sussex and the larger Clumber breed is also well known. The cocker, whose name recalls its former use in English woodcock shooting, is much smaller than the field spaniel. The best-known breeds of the latter form are the English, Welsh and Devonshire varieties. The smaller, King (or Prince) Charles spaniel, is a small variety of the spaniel, used as a lap-dog. It is sometimes found entirely black, and receives its name from the liking of Charles II for this variety. The Blenheim breed is of smaller size than the King Charles variety, and is bred merely as a pet. Its hair is long and silky, and does not curl; the ears are long, and provided with the same silky hair; the legs are covered with this hair to the toes; and the tail possesses a broad hairy fringe. The water-spaniels are dogs of moderate size, and average about 22 inches in height at the shoulders, and the ears are very long and pendulous. The Japanese pug-nosed spaniel, Maltese and other toy-breeds may be added to this list. See Doc.

SPANISH-AMERICAN ATHENÆUM.

This organization was established in Washington, D. C., in 1913 by Bishop Charles Warren Currier, Francisco J. Yanes, Dr. James Brown Scott and J. Moreno Lacalle. Its purpose is to develop and disseminate in the United States interest in the literature and history of Spain and the Spanish-American republics. Monthly meetings are held with programs contributed by diplomats, educators and travelers. One number of its "Revista" has been published. Present officers are Guillermo A. Sherwell, of Mexico, president, N. H. Darton, of Washington, vice-president, Dr. Luis Churion of Venezuela, second vice-president, Wm. T. Faulkner, secretary-general. Alfonso XIII, king of Spain, is the honorary president.

SPANISH-AMERICAN LITERATURE.

See LATIN-AMERICAN LITERATURE.

SPANISH-AMERICAN WAR. See UNITED STATES, THE WAR WITH SPAIN.

SPANISH-AMERICAN WAR, The Naval and Military Order of, an association organized in New York, 2 Feb. 1899. Its objects are to cherish the memories and associations of the war. There are State branch associations in Pennsylvania, Massachusetts and Illinois. The total membership in 1903 was 1,100.

SPANISH ART. At the beginning of any profound study of the greatest of the Spanish paintings, which were those of the 17th century, should stand the fact, the true significance of which has hitherto been overlooked by art critics, that the production of the famous ironwork of Spain trained eye and hand—taught marvelous celerity and certainty of execution—through many centuries that preceded the 17th. The Moors had expressed, with iron as a medium, not only their basic principles of design, but also the delicate and elaborate method they applied to the precious metals.

During the Romanesque and early Gothic periods French ironwork also exerted its influence in the western peninsula. Afterward, Italian Renaissance architecture, as it was interpreted and applied in Spain, gave to the ironworker such an opportunity for the exercise of his talent that he achieved grandeur and architectonic quality in his work, surpassing the attainments of iron-masters in other lands; and, if we are to appreciate the distinguishing characteristics of such pictures as the 'Spinners' and the 'Meninas,' painted after the manner of an instantaneous photograph, we must remember that the artistic ironworker was generally an expert in other arts as well, and sometimes the ancestor of a painter who thus inherited, as did Velasquez, for example, rapidity with certainty of execution, power in combination with delicacy. In this connection we may cite the following characterization of the Gothic and Renaissance ironwork: "The charm of the Gothic cannot be denied. Produced, as it were, by feverish, powerful blows delivered during the brief moment that the mass was glowing hot, it is a sort of solidified impressionism and appeals accordingly. This mediæval spontaneity, it is true, eluded the more sophisticated Renaissance worker; but not the mediæval craftsmanship. This he retained and added to by his command of newer processes and his greater knowledge of design till he had reduced the mightiest of all metals to an obedience that would have been unbelievable to his predecessors." (Consult Byne, A., and Stapley, M., 'Rejería of the Spanish Renaissance,' New York 1914, and 'Spanish Ironwork,' ib. 1915; also 'The Famous Ironwork of Spain' in the *Architectural Record*, Vol. XXXIX, ib. 1916). We shall again refer to this potent influence when we come to the third and universally significant period of Spanish painting.

Painters, Architects and Sculptors.—The attempt to trace clear national lines of development in the Spanish arts has always been regarded—and not without reason—as an extremely difficult undertaking. Spanish art is indeed like a river whose current is swollen by many a stream from as many different lands. Nevertheless it has characteristics that are strikingly—often startlingly—individual and distinctive, and these are the characteristics to which we should devote special attention. The difficulty just referred to has been increased and intensified by the undue attention that writers have paid to the numerous foreign artists who have been residents in Spain and whose works still remain there: to those foreigners who, in Spain but not sympathetically of Spain, neglected or failed to express, in and through the works of art they created, the Iberianism of the country that sheltered them and employed their talents. It has seemed to us necessary, therefore, to prepare a new list of Spanish painters, architects and sculptors, which should be based upon an independent principle of selection. We omit the names of all who do not seem to be more closely connected with the Spanish arts than with those of any other country.

Here follows the list, designedly restrained within very narrow limits and presenting the names of painters, architects and sculptors in alphabetical order: Bayeu, F., painter, 1734–95,

worked at Zaragoza, Madrid, Toledo, etc.; Becerra, G., sculptor, b. 1520 at Baeza, d. 1570 at Madrid, worked at Burgos, Astorga, Salamanca, etc.; Berruguete, A., son of the court-painter Pedro, sculptor, architect and painter, c. 1480–1561, worked at Avila, Valladolid, Salamanca and Toledo; Cano, A., painter, sculptor, architect, 1601–67, worked principally at Granada and Seville; Churriguera, J., architect and sculptor, late 17th century to 1725, worked at Madrid and elsewhere, and was succeeded by his sons Gerónimo and Nicolas; Espinosa, J. J. de, Valencian painter, 1600–80; Falcó, N., Valencian painter, worked c. 1515–76; Forment, D., sculptor, worked at Huesca and Zaragoza, c. 1511–33; Gallegos, F., painter, c. 1465 or 1475–1550, worked at Salamanca and Zamora; Goya, F. de, painter, 1746–1828, worked at Zaragoza, Valencia, Madrid and Bordeaux; Greco, El (see THEOTOCÓPULI, D.); Hernandez, G., sculptor, 1566–1636, worked at Valladolid and Plasencia; Herrera, F. (el Mozo), painter, 1622–85, worked at Seville and Madrid, and Herrera, F. (el Viejo), 1576–1656, painter, who also worked at Seville and Madrid; Herrera, J. de, 1530–97, architect of the Escorial; Leocadio, P. de (San Leocadio), Valencian painter, 16th century; Mazo, J. B. del, Velasquez's son-in-law and pupil, d. 1687; Mora, J. de, 1638–1725, sculptor; Murillo, B. E., painter, 1617–82, worked at Seville; Pacheco, F., 1571–1654, painter, instructor and father-in-law of Velasquez, worked at Seville and Madrid; Pantoja de la Cruz, J., 1551–1610, court painter to Philip II; Ribalta, F., c. 1551–1628, painter, worked at Valencia; Ribera, J. de (Lo Spagnoletto), 1588–1656, painter, worked at Valencia and Naples; Rincón, A. del, c. 1446–1500, court painter to Ferdinand and Isabella; Roelas, J. de las, 1558–1625, painter, worked at Seville; Sánchez Coello, A., d. 1590, court painter to Charles V and Philip II; Sorolla y Bastida, painter, b. Valencia 1863, lives there and in Madrid; Theotocópuli, D., pupil of Titian, painter, sculptor, architect, called El Greco because born in Crete at an uncertain date, worked at Toledo and died there at an advanced age in 1614; Valdés Leal, J., 1630–91, painter, worked at Seville; Vargas, L. de, 1502–68, painter, worked at Seville; Velasquez (or Velazquez), Diego de Silva, 1599–1660, painter, studied first at Seville, afterward identified with the Spanish court and court-circle of Philip IV at Madrid and elsewhere; Viladomat, A., 1678–1755, painter, worked at Barcelona and Tarragona; Zarcillo, F., 1707–48, sculptor, worked at Murcia; Zuloaga, I., painter, b. Eibar, 1870, lives chiefly at Segovia; Zurbarán, F., 1598–1662, painter, worked at Seville.

The names of other Spanish artists, whose works exemplify special tendencies rather than the main lines of growth or the distinctive Iberian characteristics, will be mentioned—with comment whenever that is required to differentiate their talents—in the following paragraphs.

Spanish Painting.—The history of Spanish painting falls into three main periods: First, the period of the Flemish influence; second, the period of the Italian influence; and third, the period in which the Spanish genius "found itself," gaining vastly in the power of independent art-expression, and so, with creative art-impulses freed in a measure from bondage

to foreign schools, though never wholly escaping the tyranny of national institutions, political, religious and social, finally acquired, as we said above, universal significance. About the end of the 15th century or the beginning of the 16th, the works of Antonio del Rincón at Granada and the panels of Fernando Gallegos at Salamanca and Zamora, as well as the easel-paintings and panels of the early Seville painters, Juan Sánchez de Castro and Alejo Fernández, most clearly proclaim the northern influences still triumphant throughout the peninsula, as they had been continuously, except along the northeastern littoral and in the extreme south, ever since 1435 or 1440. But the irresistible charm of the great Florentine masters was presently to be felt in Spain as in western Europe generally. A new world of artistic possibilities was revealed to Spanish art-students voyaging eastward just when Spanish soldiers and merchant-adventurers, year after year sailing westward, were engaged in exploring and conquering the New World of boundless material possibilities; and so, at this point in our study, we come upon a half-century of inspiring, fancy-stirring Spanish experiences—of a synchronous hazard of new fortunes in art and imperial expansion, in Italy and America. By the middle of the century, or just a little while afterward, the oceans and mountains, the rivers and “naked lands” had been explored, and that fever of daring ventures abated. By the middle of the century, or a little before, the methods and aims and almost—not quite—the heart of the Italian Renaissance had also been explored; and by an altogether dramatic coincidence Seville, rather than any other Spanish city, received Italy's new message, and more than the other cities appreciated it, at the very time when she was receiving at her Tower of Gold all the amazing shipments of America's treasure.

Somewhat before the days of Luis de Vargas, the Italian influence became potent at Seville, and for more than two generations, or until the close of the useful career of Francisco Pacheco, its control was not seriously contested except by Juan de las Roelas and Francisco Herrera the elder. In central Spain, meanwhile, the successors of Alonso Berruguete strove to pass from hand to hand the torch their distinguished master had kindled at the cinquecento flame, but here the efforts appear to have lacked continuity and organization. At the Spanish court the northern tradition was still far from being dislodged: to prove this a glance at scrupulously conservative portraits painted by Alonso Sánchez Coello and Pantoja de la Cruz will be sufficient. Nevertheless the court was already attentive to the appeal of Italian painting—in this instance not the Tuscan but the Venetian school. The superb collection of Venetian pictures at Madrid, begun by Charles V and increased by Philip II, made that appeal, which became a resistless one when it had thus gained the compelling force of proximity.

Now, the Renaissance spirit itself bespoke a freer quest of beauty than had ever before been conceded by Spanish realism; but the situation called for an apostle of freedom—and El Greco came. Domenico Theotocópuli (El Greco), by the independent character of his work at Toledo, by the originality he probably

advocated and certainly exemplified with wonderful success, suggested to other painters, as a not unattainable ideal, the expression of personality without slavish dependence upon any foreign school whatever in the manner of its expression. As a zealous advocate of religious and social reforms speaks, often overemphasizing his “values” in order to convince his audience, so El Greco painted, often forgetting mere truth to nature; but fortunately the early training at Venice gave him that command of color and fluency in narration that are in evidence even at such moments—perhaps especially at such moments. And of course the Venetian training counted in his favor and in favor of the acceptance of his novel theories by many Spaniards. The reason why such acceptance had become possible has been plainly stated in the two foregoing paragraphs. In Seville we find at almost the same time the progressive Juan de las Roelas and a bit later that declarant of independence, the elder Herrera, as above intimated. In Valencia the Italianized Francisco Ribalta was the teacher of Jacinto Jerónimo de Espinosa, who displayed independence in the choice of some of his themes. Ribalta also, it is much more important to note, was probably the first instructor of that exceptional painter whose great talent embraced the best characteristics of both Spain and Italy, Jusepe de Ribera, called Lo Spagnoletto. It is not too much to say that Ribera added constructive reality to Theotocópuli's inspiring but vague theories and ideals of freedom and the free expression of personality. The Toledan has predisposed; now Ribera disposed, showing to all the definite, sure path that led to greatness through the ennoblement, not through the abandonment, of the realistic bias—of the national propensity toward realism. And so we place together the names El Greco and Lo Spagnoletto. The Greek said: “Find a way.” The Little Spaniard said: “This is the way.” Together, in this sense, they usher in the third period.

Estremadura gave to Spain and the world Francisco Zurbarán, realist, unequalled portrayer of monastic types; Córdoba, a number of naturalistic painters. To the latter school belonged Antonio de Saavedra y Castillo and his pupil Juan de Valdés Leal (afterward identified with the school of Seville). Especially representative of the school of Granada at the beginning of this period are Alonso Cano (who had previously devoted his attention to sculpture at Seville) and his two pupils—or, it may be, only his most able immediate successors—Juan de Sevilla and Fray Atanasio, surnamed Bocanegra. But the school of Seville gave to Spain and to the world Bartolomé Esteban Murillo and Diego Velázquez, or Velasquez. (The latter signed his own name—and distinctly enough—in 1650 *D.D.*, that is, Diego de Silva, *Velasquez*. His mother's family name was Velázquez, but he substituted *s* for the first *z* at that time).

For our present purpose it is less essential to describe Murillo and Velasquez as the greatest of Spanish painters than to realize how differently they were affected by the 17th century influences at Seville—the new movement favoring freedom in choice of subject and realism in its treatment, while the old repressive ecclesiastical policy discouraged such free-

dom. Two striking passages in Mr. Tyler's book (see *Bibliography*) show that writer's clear apprehension of the dissimilar manifestations: "There [in Seville] sat Pacheco, appointed censor by the Inquisition, proclaiming that the one aim of art was to excite men to devotion. . . . Murillo seems to have had a temperament that naturally expressed itself through pious subjects; thus there was nothing in the air of Seville that made it stifling for him. But what of men like Herrera el Mozo and Valdés Leal? They both had detestable characters and great aptitude, especially the latter; but 17th century Seville, which was so pleasant to Zurbarán and Murillo, drove them to every sort of bitter excess." And again, the turning-point in the career of the school "was reached when the twenty-year-old Velazquez went to Madrid. Though his master Pacheco was a pedant, he seems to have been a friend to art after his own manner, and there were enough painters in the Andalusian capital to have kept a brilliant school alive, had it not been for the exaggerated atmosphere of devotion that prevailed there. Whether Velazquez would have become the man we know had he stayed there instead of travelling in Italy is open to grave doubts; at any rate the atmosphere of Seville was too close for him. He went to court, and those who stayed had to devote themselves to religious subjects or starve. Velazquez was able to paint as he pleased at Madrid." Professor Carl Justi has made the correct observation that Murillo was originally as essentially a realist as Velazquez; but for the simple reason that he continued to live in a Roman Catholic provincial town and painted for conventual churches, he "had to represent the subjects that pleased the devout of his day, such as the Immaculate Conception, the visions of the monk's cell, the mysteries and ecstasies of asceticism. He could not devote his entire energy to the reproduction of the mere visual phenomena. He had to depict what was never seen. . . . His artistic greatness, the secret of his wonderful success, lies in the fact that he recognized the unique character and special charm of the human nature of southern Spain, adapted it to the palette and the brush, and ventured to introduce it into paintings of religious subjects." Velazquez, after wrenching himself free from provincialism, discovered in himself the very special powers of another Cristóbal Andino, that greatest and most honored 16th century ironworker of Burgos, Seville and Toledo. Let us read what was written by Bonnat in his preface to Beruete's 'Velazquez' (see *Bibliography*): "The methods which Velazquez employed to obtain such startling results are surprisingly simple. Armed with a palette on which only a strictly limited number of colors appear, and with a few long and slender brushes in his hand, he painted in everything at the first touch. The shadows, much simplified, are merely rubbed in, and only the high lights are thickly painted; and the whole, with its fine gradations of tone, is so broadly and rapidly executed, and is so precise in color and proportion, so exact in its values, and so true in drawing, that the illusion is complete and the resulting work a marvel." Yet it is only proper to say that Bonnat, so far as we

know, had not given thought to the analogue or explanation that we have offered. At Madrid, the contemporaries of Velazquez, forming the Madrid School, were Fray Juan Rizi (1595-1675); Antonio Pereda (1599-1669); Francisco Rizi (1608-85); Juan Carreño (1614-85); Velazquez's successor as court-painter; José Leonardo (1616-56), and Diego Polo (1620-55). A little later came Juan Antonio Escalante (1630-70); Mateo Cerezo (1635-75); José Antolinez (1639-76); Claudio Coello (c. 1630 or 1635-93), and Sebastian Muñoz (1650-90). The capital, with its collections of paintings for study, with its more liberal patronage and interesting life, became the centre of artistic activity by 1625 and retained that pre-eminence to the end of the 17th century.

During the greater part of the 18th century Spanish art produced imitations. Señor Beruete y Moret (see *Bibliography*) even goes so far as to say it produced "nothing but imitations," then adding that "these imitations were not particularly happy." Original talent was temporarily displaced—that was all; for it was reinstated by Goya (1746-1828) whose works, taken all together, make a remarkably vivid and complete picture of the Spanish life of his day. "In the latter years of the century," writes Señor Beruete y Moret, "an original artist, Francisco Goya, arose. He cast from him all foreign influence and realized an art of his own which was so genial, so characteristic, and so Spanish that it gave evidence of the renescent artistic spirit of his country." True, that promise of renescent Iberianism was not quite fulfilled in the works of José de Madrazo (1781-1859), Federico de Madrazo (1815-94), Mariano Fortuny (1839-74), or José Villegas, b. 1848; but Sorolla (Joaquín Sorolla y Bastida, b. Valencia, 1863) depicts very brilliantly the sunlit atmosphere of his native province, while Ignacio Zuloaga (b. Eibar, 1870) summons the Spanish people and landscapes to appear on his canvases as though he were a magician. Zuloaga's talent exemplifies the obligation of Spanish painting to Spanish metalwork. His birthplace, the Basque town of Eibar, is called the "Toledo of the North" because the occupation of its people is to temper and damascene sword-blades and poignards. His great-great-grandfather, Don Blas Zuloaga, was an excellent armorer and a friend of Goya; his grandfather, Eusebio, also a famous armorer, organized and directed the Royal Armory at Madrid; his father, Plácido Zuloaga, revived the art of inlaying metals. Consult Frenzi, G. de, 'Ignacio Zuloaga' (Rome 1912).

Architecture.—The best single point at which one can subject works of architecture of all the Spanish architectural periods to direct and personal observation is undoubtedly the ancient city of Toledo, since all such periods are represented in its structures, and represented by good examples. But Mérida in the southwest possesses the most interesting architectural memorials of the Roman Empire, as Asturia in the north possess those of the Visigoths. During the Roman period imperial public buildings were very numerous in Spain; and although comparatively few escaped destruction their massive dimensions and characteristic lines exerted an influence in the

formation of national taste that has never been wholly lost. Again, between 414 and 711 (the Visigothic period) another controlling influence was felt; and this is far from being unworthy of our consideration, inasmuch as, among all the hordes that invaded Spain in the 5th century, the Visigoths, natives of Dacia, the modern Rumania, were, as Mr. Tyler says, already Christians, and by far the most advanced in the arts of war and peace. Mr. C. H. Blackall writes (in Sturgis, R., 'A Dictionary of Architecture and Buildings,' New York and London 1905) that the invasion of the Visigoths appears to have swept away nearly all the architecture of the Roman period, while the conquest by the Moors, in the early part of the 8th century, in its turn obliterated most of the remains of the Visigothic work, except in the north. Then, "the seat of government being fixed about Madrid, the Renaissance style, which was imported from Italy and fostered by constant intercourse with foreign artists, was naturally at its best on the central plateau." In the central portion much of the mediæval work "disappeared to make room for the Renaissance palaces. In the south the Moors found little to preserve when they first entered the kingdom," and the architectural work that they themselves did was of such manifest value that it was, on the whole, very little disturbed subsequently. We, therefore, find the Gothic and Romanesque chiefly in the north, the Moorish in the south and the neoclassic along the central plateau.

The mosque at Córdoba, the oldest and largest Moorish monument in Spain, founded in 785; El Cristo de la Luz at Toledo, and in the same city the Casa de Mesa and the Taller del Moro; the Giralda tower (1196) at Seville; the Alhambra at Granada—these are familiar examples of Moorish work before the reconquest. The name Mudéjar is given to that blending of the Christian and Moorish styles which took place after the reconquest. The Romanesque, introduced toward the end of the 11th century, prevailed throughout the 12th. Examples of this are, beside that famous resort of pilgrims in our own day, the church of Santiago de Compostela (1060-96),—Sant' Isidro in León (1063-1149), San Pedro at Huesca (1100-1241) and the cathedral of Lugo (1129-70). Not long afterward the Gothic was introduced from France, and as examples we may mention the churches of Viruela and of Las Huelgas, the latter built by Ferdinand III about the middle of the 13th century. But the Gothic at first failed to maintain itself as French-Gothic in Spain: it became Spanish-Gothic, actually composite, by the union in the same structure of the new Gothic principles with the Romanesque, or those of a still older period. Such are the churches of Salamanca (1178) and Santa Maria at Benavente (1170-1220). Not before the 13th century could the pure, perfected French cathedral style make an irresistible appeal. It was adopted and magnificently shown then in the cathedrals of Burgos (1221), of Toledo (1227), and of León (1250-1305). The cathedral at Seville, largest of all Gothic churches, was founded at the beginning of the 15th century. The end of the same century witnessed the erection of buildings of extraordinary originality and picturesque charm which, as Professor Carl

Justi writes, "mirror that mighty outburst of national feeling which followed in the train of a series of unparalleled events." Noteworthy among the structures of this group are the façades of San Gregorio and San Pablo at Valladolid and of Santa Cruz at Segovia.

The Renaissance came to Spain almost a century later than to Italy. Here "the essential point of contact was in the domain of decoration; artistic imagination, accustomed to Mudéjar and Gothic ornamentation recognized in the new style a new class of motives, enlarging its previous range." An important example is the coro of the cathedral of Córdoba, although this had been begun in 1523 in the Gothic style. So suggestive of works in the precious metals was the new manner of ornamentation that the term Plateresque (from *platero*, meaning silversmith) was given to it. An honored name among architects at the time was that of Diego de Riaño (d. 1533), who designed the Sevillian city hall and portions of the cathedral; representatives of a reaction in favor of severity and restraint, advocating the attainment of more stately effects through proportion alone, without decoration, were Juan de Toledo, who began the Escorial, and Juan de Herrera, who completed that huge late-Renaissance structure. In the 18th century the Churrigueresque, a style peculiar to Spain and Spanish colonies, ran riot (see CHURRIGUERA in foregoing list of painters, architects and sculptors) and the canons of classic design were disregarded. "Stucco and gilding were lavishly used," says Sturgis, "and broken pediments, twisted shafts and contorted scrolls abound. The result is, like nearly all Spanish work, highly decorative and not without a certain theatrical splendor, but it lacks structural reasonableness. About 1700 a more academic style began to displace the Churrigueresque." Best of the 18th century "more academic" buildings is the Royal Palace at Madrid, a dignified and well-balanced composition. In the 19th century and thus far in the 20th, eclecticism has been the rule. It has seemed the part of wisdom, in a country so rich in varied traditions of art, to reproduce approved old forms rather than minister to the craving for novelty.

Sculpture.—In the Renaissance period the Italian influence was overwhelming and during many years the marble-cutters of the better class were almost exclusively natives of Italy. This circumstance has occasioned general acceptance of the theory that, during earlier and later periods as well, this or that foreign influence usurped the place lawfully belonging to original Spanish talent. We shall try to indicate the correct limitations of such a theory, in the course of a brief review of the main essential facts.

And first we must realize that native works of great merit, such as those of Pedro of Tarragona in the Tarragon Cathedral, date from 1426, 1434 and so on; that Bartolomé's *apostles* at the main door of the same cathedral date from 1278; and that the Apostles' Door at the cathedral of Burgos was also executed in the 13th century. In other words, Spain did not wait for the coming of the Italian Renaissance, or for its long-delayed arrival at her shores (end of the 15th century), but on the contrary created ideal figures, portrait statues and whatever was required for the embellishment of

architectural design, long before Italianization prevailed. French influences are evident in some of the sculptures of the 13th and 14th centuries; Netherlandish influences in some of those of the 15th century. But an art critic should not fail to observe the relatively small number of those sculptures which belong to the schools mentioned and may properly be called foreign products. He will perceive Spanish realism, with its directness and forcefulness of expression, stamping as Iberian the vast majority of early sculptures, down to or even beyond the middle of the 15th century. Gil de Siloe, toward the end of that century, produced such sculptures as the monument in honor of Bishop Alonso de Cartagena at Burgos and the well-known works at Palencia and in the Cartuja de Miraflores. A few years afterward, however, the supremacy of Italian sculpture was recognized. Bartolomé Ordóñez frankly employed Italian assistants, and was working with them at Carrara when he died (1520). Alonso Berruguete, who returned from Italy in the year of Ordóñez' death, was a versatile artist whose impulse, on rare occasions, to regain originality led to extravagances; but his chief work (if we accept Professor Justi's view to this extent) "shows how deeply he had steeped himself in the spirit of Michelangelo." Damian Forment and Diego Morlanes were inspired by Italian and classic ideals.

The period of complete emancipation arrived when Spanish sculptors chose wood as a convenient substitute for stone—a period or epoch during which was accomplished a revolution in ecclesiastical taste that is peculiar to Spain. The enthusiasm for figure sculpture grew into a marked predilection for bulk and multiplicity of detail; and "one result of this was that stone-carving was practically abandoned, and the artist confined himself almost exclusively to wood (pine, cedar, linden, larch) as a cheaper and more easily worked material. Coloring was not used at first. Now arose those huge retablos which cover a choir-wall reaching up to the vaulting with a Jacob's Ladder of statues. All that had been expressed in the 14th and 15th centuries by small painted groups and panels was now translated into lifesize statues." Miguel de Ancheta made a retablo containing 35 statues and groups. Gaspar Becerra was one of the most famous sculptors (in this medium) among Castilians. In Seville, at the beginning of the 17th century, Martinez Montañez, in whose works there is not a trace of the Italian style, or indeed of any other foreign influence, led popular interest in and appreciation of polychrome sculptures, whose art is "the result of an essentially Spanish attitude of mind, while the sense of form through which it is expressed is probably peculiar to Seville." The polychrome figures did not, however, represent the best achievements in this distinctively Spanish phase. Pedro de Mena, a sculptor of Granada in the last half of the 17th century, carved statues and statuettes that required no paint to enhance verisimilitude. The unpainted small wooden figures of saints by this artist are remarkably original, as all critics will admit. But they show more than independence of foreign schools: they show such marked superiority that foreign students of art may learn the fine secret of true characterization by visiting the

cathedral at Malaga and copying Mena's sculpture there.

It seems to us that the story of enfranchised Spanish sculpture—often wholly or in a measure free and sometimes lawless, ungovernably Iberian, as in the days of Churriguera and those of Francisco Zarcillo (1707-48), Arismendi, and Ron—reaches its true climax when Mena's success is recorded. A classic reaction of no genetic value at the beginning of the last century resembled what took place in France at the same time. The present century witnesses reassertion of the national tradition, in this art as in the art of painting, and now looks for an exponent of Spanish realism who, as sculptor, shall stand beside the painter, Ignacio Zuloaga.

MARRION WILCOX.

SPANISH BROOM, a leguminous papilionaceous shrub (*Spartum junceum*), a "switch plant," characterized by bunches of rod-like branches, terete, polished and green. The branches are without foliage, serving as organs of assimilation; or they may have small lancet-shaped leaves, scantily developed and quickly falling. The Spanish broom is native to the Mediterranean shores, where it grows in masses, as may be seen on Gibraltar, on dry and rocky ground. It has been naturalized in tropical America, and cultivated for the terminal racemes of large pea-like flowers. These are an inch long, golden yellow and very fragrant, with the odor of acacia, and are a favorite food of bees. They also yield a yellow dye. The tough twigs are used as food for goats, and produce a coarse fibre; the seeds, from linear pubescent pods, are diuretic and tonic and in larger doses emetic and cathartic.

SPANISH ERA. See EPOCH.

SPANISH-FLY. See BLISTER-BEETLE.

SPANISH FORT, a part of the defenses of the city of Mobile, Ala., during the Civil War; taken by the Federals 8 April 1865. It consisted of a system of fortifications, rather than a single fort. On 27 March it was invested by Union troops, A. J. Smith's corps, on the right, and Granger's on the left; a bombardment was begun 4 April, in which the gunboats on the river joined, and a naval battery on shore rendered service. The Federals intended to assault the defenses on 9 April; but on the 8th General Carr found that it was possible to place a battery on a wooded crest commanding the fort and that evening his troops gained the crest, captured 300 yards of the works and, getting their battery into position,

compelled the Confederates to evacuate. Consult 'Battles and Leaders of the Civil War' (Vol. IV).

SPANISH FOWLS. See POULTRY.

SPANISH LANGUAGE. The. Spanish is one of the modern spoken and written forms of Latin, that is, it is a neo-Latin or Romance language. Its motherland is Spain in the Iberian Peninsula. Besides Spanish two sister Romance tongues are in use in the peninsula, viz., in the western part, Portuguese (which is never to be regarded as a dialect of Spanish), and, in the eastern part, Catalan (which has affinities to the Provençal of southern France). In part of northern Spain and in the district of the Pyrenees the native speech is Basque, which has no discernible relationship to its neo-Latin neighbors, Spanish and French, and is thought by some to be a survival of the ancient Iberian language. In Galicia, which occupies the northwestern corner of Spanish territory, the natural idiom is Galician, and it is a dialect of Portuguese. In the Middle Ages both Catalan and Galician had literary manifestations of no little importance. In spite of school influence, which tends to spread the influence of Castilian to their detriment, they continue to be the popular spoken languages of their districts, and Catalan has continued to have its notable writers of both prose and verse down into our own times.

In the strictly Spanish-speaking region three dialectal divisions are marked, viz., (1) Castilian-Andalusian in the centre and south of the land, (2) Leonese-Asturian in the west and north, and (3) Navarro-Aragonese in the northeast and east. Through political importance and as a result of various other reasons, especially the greater activity of its writers in the earlier period, Castilian soon became the dominant form of Spanish and remains such to-day. The term "Castilian" is often used as the equivalent of "Spanish" to designate both the language and the literature. Some have regarded Andalusian as an individual dialect, but it differs so little from Castilian—one of its most distinctive traits is its assimilation of *c* (before *e* and *i*) and of *z*, which Castilians pronounce as voiceless interdental *th*—that there is little need of giving it a place apart. For literary purposes the Navarro-Aragonese and the Leonese-Asturian have never received any extensive or lasting development.

The following may serve to illustrate some of the phonological differences between the two dialects and the standard Castilian. They both have a glide-sound between *e* and *a* following vowel, where Castilian has none: *leyer*, "to read," Cast., *leer*; *leyal*, "loyal," Cast., *leal*. They both have palatalized *ll* (the *li* of English "*filial*") approximates to this sound) where Castilian has a *j* (a guttural spirant; cf. the Scotch *ch* in "loch"); *fillo*, "son," Cast., *hijo*; *ovella*, "sheep," Cast., *oveja*. They both have *it* where Castilian has *ch*: *dereito*, "right," Cast., *derecho*; *muisto*, "much," Cast., *mucho*. The both develop diphthongs out of accented Latin short *ē* and *ō*, where Castilian fails to do so (because of the influence in Castilian of a following palatal): *pueyo*, "height"; Cast., *poyo*; Latin *pōdium*: *fuella*, "leaf"; Cast., *hoja*; Latin pl., *folia*, etc. Leonese changes *l* after a consonant to *r*: *branco*,

"white," Cast., *blanco*. Aragonese keeps initial Latin *pl* and *cl* where Castilian changes them to *ll*: *plorar*, "to weep," Cast., *llorar*; *clamar*, "to call," Cast. *llamar*.

In morphology the dialects have also certain traits that distinguish them from Castilian. Thus Aragonese tends to create a feminine form in *-a* for adjectives which are not entitled historically to that ending: *doliente*, "grieving," fem., *dolienta*, Cast., *doliente* for both genders. Leonese uses fuller forms of the definite articles: *el, ela, los, elas*: cf. Cast., *el, la, los, las*. Leonese has *-er* infinitives where Castilian has *-ir*: *viver*, "to live," *dizer*, "to say," Cast., *vivir, decir*. Castilian has no separate possessive form for the plural possessive "their," but uses *su, sus*, which also means "his," "her," etc.; Aragonese uses *lur, lures* (cf. French *leur, leurs*) as a distinctive form for "their."

By colonization and conquest Spanish has been carried to foreign regions. The explorers and settlers took it to the New World, where it is now used by hardly fewer than 50,000,000 of persons in the western continent and adjacent islands, from Mexico southward. For that matter it is still spoken even in tracts of the United States, e.g., in New Mexico, California, Texas, etc. It followed the Spanish flag to the Canaries and the Philippines, without, however, displacing the aboriginal speech in the Philippines any more than it has done so in the parts of America in which the Indians are numerous. In Spanish America the pronunciation reveals traits that once existed in Castilian of the 15th and 16th centuries and have since changed in the motherland, and it shows also features of the dialects of the portions of the peninsula whence the settlers came. But to all intents and purposes, since the dialectal differences operate for only a restricted number of sounds and the accepted principles of grammar are those of Castilian, the Spanish of Spanish-America is properly enough denominated by the generic, if somewhat elastic, term of "Castilian." The expatriated Moors and Jews have taken Spanish to places in northern Africa and in Turkey, where they still speak it in a more or less contaminated form. It is safe to say that in the neighborhood of 70,000,000 human beings are to-day using Spanish in various parts of the world.

Castilian, the standard form of Spanish, attained to the dignity of a literary medium by the 12th century, about or soon after the middle of which there appeared the noble epic poem, 'El Cantar de Mio Cid,' and the little liturgical play, 'El Misterio (or Auto) de los Reyes Magos.' But in legal, ecclesiastical and other documents we can trace its evolution, during some five or six centuries prior to that time, from the popular Latin of the more or less illiterate soldiery and colonists brought to the peninsula as a result of the Roman conquest. By the time of Augustus the conquest had become an achieved fact, and during the four centuries of peace that followed his reign the Romanization of the land, so thoroughgoing for its institutions and customs, was a practically complete process for its speech also. It is dubious that, apart from a very scant number of debatable elements of the lexicon, any vestiges of the idioms of the original Celtic and

Iberian tribes remain in the Castilian language. Vulgar (popular) Latin is the all-important source of its lexicon, phonology, morphology and syntax. In the course of time its vocabulary has been enriched by accretions from Arabic—brought in by Moorish conquest from 711 on—from other European languages, especially French and Italian, and from the Indian and other native languages of the colonial settlements.

Phonology.—With the invasion of the Germanic barbarians and the fall of Rome, in the early 5th century, political contact with Italy was severed, and the Vulgar Latin of Hispania began to undergo the changes in sound that produced ultimately Castilian in the high plateau of the centre of the peninsula.

In the following statement of facts we are concerned only with popular developments: words of peculiarly learned use did not necessarily go through the popular phonological processes.

In the vowel system it is notable that, under the accent, Latin *o* (long and short), *ē*, *ī*, *ō*, *ū*, were represented in the Vulgar Latin enunciation by close variations of the same sounds, i.e. qualitative distinctions, as between open and close utterance, became important for them as for all vowels. Latin *ī* became Vulgar Latin close *e* also, and Latin *ū* became close *o*. With their close pronunciations these vowels remained in Castilian unless affected by some adjoining sound (notable a palatal): Latin *mātrēm* (the oblique case and not the nominative is the basis of the Spanish word), "mother"; *pātrēm*, "father"; *plēnum*, "full"; *bībīt*, "drinks"; *filium*, "son"; *formōsum*, "beautiful"; *lūtum*, "mud"; Cast., *madre*, *padre*, *lleno*, *bebe*, *hijo*, *hermoso*, *lodo*.

Accented Latin *ē* and *ō* diphthongized to *ie* and *ue*, in both open and closed syllables: Latin, *vēnit*, "comes"; *fērrum*, "iron"; *mōvet*, "moves"; *fōrtem*, "strong"; Cast., *viene*, *hierro*, *mueve*, *fuerte*. This is one of the distinctive features of Castilian as compared with the other leading Romance languages, French, Italian and Portuguese; for in these latter the diphthongization occurred not at all (as in Portuguese) or only in open syllables (as in French and Spanish); cf. Cast., *fuerte*, "strong," with Ptg. *forte*, French *fort*, Italian *forte*, and Spanish *viento*, "wind" from Latin *vēntum* with Ptg., *vento*, French *vent*, Italian *vento*. A following or preceding palatal might prevent the diphthongization of the *ē* and *ō* or work further changes in a diphthong already produced from them. The Latin diphthong *ae* was treated like Latin *ē*, *cælum*, "heaven," Cast., *cielo*, *au* like Latin *ō*, *aurum*, "gold," Cast., *oro*; the few cases of Latin *oe* present some difficulty. Latin *foedum*, "ugly," Cast., *feo*, Latin *foenum*, "hay," Cast., *hieno*.

In the initial position in the word the vowels and diphthongs of Latin leveled away distinctions of quantity and quality and became simple *a*, *e*, *i*, *o*, *u*, which, in some cases underwent modification through adjacent vocalic or consonantal influences. In the final unaccented position the vowels simplified still further to Castilian *a*, *e*, *o*, in truly popular treatment. In the unaccented penult of words stressed on the antepenult the vowel *e* (Latin *ī*) usually disappeared; in the final unaccented

syllable it could also disappear after consonant sounds which the genius of the language permits to end a word.

The consonants of Latin have proved more persistent in the initial position in the word than elsewhere; but a characteristic of Castilian is the change of *f* before a vowel (but not before the Castilian diphthong *ue*) to Old Spanish aspirate *h* (still written *f* in the older stages of the language). In modern Castilian the written *h* is silent, except for a possible slight aspiration before *ue*: cf. Latin *filium*, Old Spanish *fijo*, modern *hijo*, with *fuerte*. Initial consonant plus *l* has yielded palatal *ll*: Latin *clamare*, "to call," *flamma*, "flame," *plorare*, "to weep," Castilian *llamar*, *llama*, *llorar*. Initial *r* has become a well-trilled sound, and this same sound is rendered by *rr* between vowels. Another characteristic of Castilian is the conversion of both Latin *b* and Latin *v* (*u* in hiatus) to a single bi-labial spirant sound written either *b* or *v*: the sound of English *v* does not exist in Castilian. Latin *c* before *e* or *i* assimilated in Old Spanish to *ç* or *s*, which now, whether written *c* or *s*, mean the interdental sound of English *th* in "thin." In the intervocalic position a Latin single voiceless consonant is voiced: e.g., *t* became *d*, *p* became *b*, *c* became *g* (before any vowel but *e* or *i*); but intervocalic *s* is always voiceless in modern Spanish. Consonantal combinations between vowels were subject to a variety of changes not easily epitomized, but simplification was the usual process. The doubling of the same consonant is not a feature of modern Spanish; it is found only in the cases of *cc* and *nn* and both of the *c*'s and the *n*'s must be uttered, as in *facción*, "faction" and *innoble*, "ignoble"; *rr* denotes a reinforced *r* sound, while *ll* denotes a palatalized sound and is not a doubled *l* in value; *ñ* (*n* with a *tilde*) means a palatalized *n* (approximately the *ny* of "canyon" from Castilian *cañón*). Of the consonants actually final in Latin the commonest were *s* and *t*; of these *t* was lost, Latin *amat*, "loves," Castilian *ama*, while *s* has remained and is very useful as a flexional sign (it marks the plural of substantives and the second person of verbs, Latin pl. *partes*, "parts," Castilian *partes*; Latin *amas*, "thou lovest," Castilian *amas*).

Accent.—The stress in the Castilian word may fall on the final syllable, the penult or the antepenult; occasionally it may fall upon a syllable more than three places removed from the end of the word. All words not stressed on the final or the penult must have a written accent. Words ending in a consonant except *n* or *s* normally stress the last syllable and need no written accent; those so stressed and terminating in *n* or *s* must have the written accent. Words ending in a vowel or diphthong and stressing the penult need no written accent; but all words stressing a final vowel or diphthong require the written accent thereon.

Morphology.—For substantives a great simplification has occurred in the passage from Latin to Castilian, in that the six cases of the noun and adjective have been reduced to one in Castilian, and this usually corresponds to the Latin accusative singular and plural. Latin genitive, dative and ablative relations are rendered by combinations of prepositions with the

single Castilian form; *del hombre*, "of the man," Latin, *hominis*, etc. In the personal pronouns there are still certain case distinctions: *yo*, "I," *me*, "me," *a mí*, "to me," etc. There are no neuter nouns in Castilian; the Latin neuters become masculines for the most part, but a few become feminine.

The verb system also shows a reduction of the complex system of Latin inflections, but it still possesses many and varied conjugational forms. The Latin passive voice disappeared; its place has been taken by periphrases with the passive participle or by a reflexive or other construction. The Latin future indicative tense did not survive; it was replaced by a new form made by adding the present tense of Castilian *haber*, "to have," to the infinitive of the main verb: *amar*, "to love," plus *he*, "I have," *amaré*, "I shall love." Suffixes derived from the imperfect indicative of *haber* are used similarly to form a past future (or conditional) on the infinitive of the main verb as a base. Castilian perfect tenses are formed by combining tenses of *haber*, "to have," with the past participle of the main verb; *he amado*, "I have loved." The Latin imperfect subjunctive was lost, but Castilian has two such tenses (ending in *-se* and *-ra* in the first singular), of which the one comes from the Latin pluperfect subjunctive and the other from the Latin pluperfect indicative. There is a future subjunctive, derived from the Latin future perfect indicative and perfect subjunctive; its use has become greatly limited in recent times. Conventionally we speak of three regular conjugations in Castilian, denoted usually by their infinitive endings, *-ar*, *-er*, *-ir*; in point of fact the endings of the *-er* and *-ir* conjugations are the same for all except four of their many forms, so that the Latin four conjugations have virtually been cut down to two. A number of verbs are perfectly regular as to their endings but show certain variations in their root vowels; they form what are known as the radical-changing classes. There are no few irregular verbs.

Syntax.—There are interesting phenomena that might be considered here, but the present purpose may be served by calling attention to one of the most decided peculiarities of the Spanish language, its use of the preposition *a*, "to, at," before a noun denoting a specific person, higher animal or personified thing and standing in the accusative relation to a verb: "I see the man" is *veo al hombre* (literally, "I see to the man"). The order of words in a Spanish clause is a very elastic matter. In general the English declarative order of subject, verb, object, is but little adhered to; in a simple statement of fact the verb or the object may begin the clause, so that inversion is frequent in the language.

SPANISH LAW. The system of jurisprudence and judicial practice as developed in Spain and later extended to the Spanish West Indies, Central America, Mexico, the Spanish-speaking countries of South America and the Philippines. It is one of the oldest systems of law, and as at present constituted is a mixture of Roman, Germanic and Arabic elements, with marked traces of the influence of canon law.

Roman law became dominant in Spain as early as 200 B.C. and retained its supremacy practically until the conquest of the Visigoths, after which the Germanic law coexisted with the Roman law. There were several codifications of the law before the year 653. The Arab conquest of the 8th century was an important factor in modifying Spanish law. About 1265 Roman and canon law became prominent. Then succeeded several centuries of struggle for supremacy between the native and the Roman law. The various codes existing at this time caused great confusion in the positive law, and unsuccessful attempts were made to simplify it during the reign of Ferdinand and Isabella (1490-1502). Later the Justinian and canon laws spread rapidly throughout many of the kingdoms of the peninsula. In 1567 a general code was promulgated. A peculiarity of Spanish legislation is that no code has ever been promulgated to repeal the old codes, and the result has been difficulty in interpreting the existent law.

At the adoption of the constitution of 1876, which is now in force, civil, commercial, criminal and military law have been incorporated into separate codes. Likewise a judiciary act and codes of civil and criminal procedure have been adopted. In 1910 a commission was appointed to revise and recodify the procedural, penal and civil codes and the judiciary laws.

The Spanish civil code was promulgated by decree in 1889, and extended to the colonies later in the same year. It is still in force. This code, which is divided into four books, deals with corporations, the law of persons, marriage, guardianship, law of property, contracts, jurisdiction, conflict of laws, etc. The subject of marriage was formerly left to the canon or ecclesiastical law, but under book one of the code of 1889 civil marriages are permissible, with the important qualification that all persons who profess Catholicism must celebrate the canonical form. The third book of this code provides that no private property shall be taken for public use without due compensation—an exact counterpart of the principle made familiar in the United States by constitutional provisions. A noticeable feature of the Spanish law in regard to the descent of property and succession makes it illegal for a parent to disinherit legitimate children. Two-thirds of the estate is thus reserved. Some criticism has been aimed at the code of 1889, among others that it is incomplete. As instances it is said to contain nothing regarding certain prior laws such as those relating to mines, hunting, fisheries and civil registry. In addition it leaves questionable the relation of non-Castilian legislations and the customary law to the civil code. With the exception of the subject of marriage this code has only subsidiary force in the provinces of Aragon, Catalonia, Navarre and the Balearic Isles. The Roman law, civil and canon, is still subsidiary law in Catalonia.

The commercial code, owing to imperative need, antedated the civil code. Spain is said to have produced the first code of mercantile law in the "Ordinances of Bilbao" (1737), which spread to America and remained in effect in Mexico until 1884. Spain codified commercial law in 1830. The great commercial development of the country late in the 19th century emphasized the need of reform, and in 1885 a new code went into effect, which later in the same year was extended to Cuba and Porto Rico. Much supplementary legislation has been enacted in late years. The commercial code treats of commerce and registry, commercial contracts, banking, railroads, insurance, mercantile guaranties, commercial paper, maritime commerce, shipping, insolvency, bankruptcy, limitation of actions in commercial affairs, etc.

Civil procedure is governed by the act or code of 1881, as amended, and the judiciary act of 1870, as amended in 1882. The code of 1881 in amended form was extended to Porto Rico in 1885 and to the Philippines in 1888. Procedure in commercial cases is governed by the code of civil procedure since commercial courts were abolished in 1868. The code of civil procedure, which is arranged in three books, contains some provisions in conflict with the civil code, which was enacted subsequently. Spanish civil procedure is divided into two classes according to the nature of the action, contentious (*contenciosa*) and voluntary or non-contentious (*voluntaria*). Voluntary jurisdiction is used when there is no contention between the parties, but judicial proceedings are necessary to fix legal rights, as in cases of guardianship, administration, adoption and the like. This resembles the non-contentious jurisdiction of France, Germany and other countries of Europe. A rather remarkable feature of the code is that it provides for arbitration of civil actions out of court. Special provisions are also made in this code for procedure in voluntary jurisdiction in commercial cases.

Notarial law is of more importance than in Great Britain or the United States. Under Spanish law nearly all deeds, contracts and important agreements must be certified by a notary.

Military and naval courts of Spain have ampler powers than in the United States. The military law is governed by the code of military justice promulgated in 1890. Naval jurisdiction is considered as belonging to the military establishment, but is largely governed by the penal code of admiralty of 1888. There are no separate admiralty courts in Spain for civil cases, the ordinary tribunals having jurisdiction of such suits.

The ancient Spanish codes treated the subject of criminal law quite completely. Formerly the laws were unusually harsh, but during the 19th century, in keeping with the spirit of the times, many reforms were introduced, some as early as 1812. The present code, authorized by the act of June 1870, made only a few material changes from the code of 1848. Modifications of the present code were made in 1876, 1904 and 1908. An amendment of this code was extended to Cuba and Porto Rico in 1879 and to the Philippines in 1886. The Spanish criminal law classifies offenses according to their nature into felonies, crimes and misde-

meanors. Punishments are classified as afflictive, correctional, light and accessory. The first class commences with death and includes numerous forms of imprisonment down to disqualifications. The second class includes imprisonment and arrest, public censure and suspension from the privilege of holding certain offices or pursuing certain callings. The lighter forms of punishment include arrest and private censure. In any of these three classes offenders may also be fined or put under recognizance. The accessory punishments include payment of costs, civil interdiction and degradation. Until modern times the system of criminal procedure under the codes was the secret and written procedure, the hampered defense and torture. This system was reformed by the code or act of 1882, which substituted the accusatory system. This code to date has had few amendments. It was extended after amendment to the Philippines, Cuba and Porto Rico, where it became effective in 1889. Among the most important changes in procedure in Spain in recent years was the re-establishment of the jury in criminal trials in cases of felonies and some misdemeanors (1888), but it has not been extended to Cuba, Porto Rico or the Philippines; nor is it employed in many of the Mexican states or in the remaining Spanish-American countries. Every trial involving the more serious offenses is commenced by a *summario*, which resembles the secret investigation of a grand jury, after which the accused is kept in solitary confinement while an *ex parte* investigation is made by a judge of the first instance and the state's attorney (*fiscal*). Proceedings based on the constitutional provision prohibiting the detention of accused persons except for just cause somewhat resemble *habeas corpus* proceedings of the United States and Great Britain.

The judiciary act, comprising 932 articles, supplemented by special statutes, makes provision for the various courts. There are three grades of civil courts: Courts of the first instance, courts of appeal and the Supreme Court, which sits at Madrid. Jury trial is not employed in civil cases.

Spanish law differs radically from that of Great Britain and the United States in having no judicial legislation (so-called "judge-made law"), the decisions of none of its courts having binding power as precedents.

The official legislation of modern Spain commenced, it may be said, with the convening of the Cortes in 1810, and two years later the first constitution was promulgated. Previous legislation consisted of edicts of the kings with codes of law authorized by royal decree. The Supreme Court was authorized by the constitution of 1812, but it was not finally organized until 1834. An important reform in the criminal law was made by the act of 1908, relating to conditional sentence, by which, under certain circumstances, sentences may be suspended. Capital punishment still exists, although many efforts have been made to abolish it. Another feature of modern legislation provides in case of wrongful convictions, under certain circumstances, that the judges are held civilly liable. In late years Spain has enacted many laws providing for social and economic reform. Among them may be mentioned a workmen's compensation act (1900); industrial courts to

adjust differences between employers and employees (1908); a national institute for old-age pensions (1908); regulation of employment of women and children (1900-08); recognizing the right of employers to organize and of employees to organize and strike, and fixing penalties for inciting employees to strike. Other legislation of a similar nature is still (1918) pending.

EDWARD F. DONOVAN.

SPANISH LITERATURE. For the sake of convenience the history of Spanish literature as written in the motherland may be regarded as constituting four chronological divisions, namely, the Old Spanish period, extending from the 12th century down to the 16th; the Golden Age, which runs through the 16th and 17th centuries; the period of the 18th century; and the more recent period, which reaches from the beginning of the 19th century to the present moment.

Old Spanish Period.—Heroic tradition informs the most noble composition that the Middle Ages have bequeathed to Spain, the 'Poema del Cid' (or 'Cantar de Mio Cid'). This seems to have taken form by the middle of the 12th century or not long after that date, and as is unfortunately the case with still other notable works of the Old Spanish period, it is preserved to us in but a single manuscript, which is in a badly garbled condition. Belonging to the 14th century and being, therefore, about a century and a half later than the original composition, this manuscript must not be deemed a faithful transcript of the poet's labors; in all probability it reflects many of the linguistic and other features of the scribe's own time. As it stands, the document has some 3,700 odd lines. These are usually bound together into stanzas or *laissez* (to use a term employed to designate a similar arrangement in Old French epic poetry) of irregular length, with vocalic rhyme or assonance as the binding principle. In the manuscript the lines vary greatly as to the number of syllables that they contain; some lines are very long, others are very short. As a result there are scholars who consider the poem as having been ametrical in the inception. It is possible, however, to argue that the original document was perfectly metrical and to say that its present metrical irregularity is due to imperfect redaction and to scribal bungling. On the basis of facts derived from internal criticism and in consonance with a feeling that the true Old Spanish heroic measure was the same that is still seen in the *romances* or ballads (the oldest of which are heroic in nature), it is not unwarrantable to declare that the author of the 'Poema del Cid' used long verses of 14 to 16 syllables each, and that the individual verses broke regularly into half-lines with a verse stress on the seventh syllable in each half-line. Mingling fact and fiction, the 'Poema' is a fine epic dealing with the career of a great Castilian hero, who lived in the 11th century, Rodrigo or Ruy Diaz de Bivar, who received the title "Cid," "Lord," from the Moors. We see him passing into exile at the behest of his monarch, Alphonso VI of Castile and Leon, engaging in battle with both Moor and Christian, and assuming control of Valencia, after he has taken it from the Moor.

The element of fiction seems to be the prevailing one in another document, the 'Crónica rimada del Cid,' apparently of the 14th century. This (termed also the 'Rodrigo') is deemed by some a chronicle in verse, while others do not hesitate to call it an epic or at least an aggregation of epic ballads. Its narrative relates especially to the early life of the hero; its form exhibits a disturbance of verse conditions no less serious than in the case of the 'Poema del Cid.' A still older hero, the valorous Castilian Count Fernán González of the 10th century, is celebrated in a school epic (back of which there was probably a more popular composition) of the 13th century. It is in monorhymed quatrains of alexandrines,—a form of verse which now gained favor for narrative purposes and maintained itself in vogue for some time—and it is not preserved in its entirety.

Such are the documents regularly cited as examples of Old Spanish epic composition; no others appear to have survived. But Old Spanish heroic tradition was certainly more extensive and treated of still other warriors and their deeds. Whether this was done in poems of some length or only in brief epico-lyric compositions or ballads is a matter under discussion, but at all events we know that during the Middle Ages the *juglares* or minstrels of Spain entertained both nobles and commoners with their versified accounts of the exploits of various heroes besides those already mentioned. These versified accounts have passed from view, but the substance of them—with occasional retention of verses of the originals—are found in prosified form in the 'Crónica General,' which was begun at the incentive of King Alphonsus X of Castile in the 13th century, so that this great chronicle is aptly styled a treasure house of Old Spanish heroic tradition. On the basis, then, of material preserved in the 'Crónica General' we may assume that older Spain possessed heroic song about the Seven Infantes de Lara; about an Asturian hero, one Bernardo del Carpio; about certain descendants of Count Fernán González; about Roderick the Goth, whose criminal love is said to have brought on the invasion of Spain by the Moors; and about Charlemagne, who is alleged to have been a youthful exile in Saracen Spain. It may be stated here that from the 15th century on all the heroic figures enumerated play a part in the rich balladry of Spain that is actually preserved.

The oldest known drama in Spanish probably came into existence at about the same time as the 'Poema del Cid.' It is a brief mystery play in rather elaborate verse form on the visit of the Magi to Bethlehem, and it seems to derive from a Latin original written in France. But from the 12th century down to the middle of the 15th no other Spanish play has survived; there is, however, unmistakable evidence that pieces both religious and profane in nature were performed during the interval.

The first Spanish poet known to us by name, Gonzalo de Berceo, made his appearance in the first half of the 13th century. Berceo showed his genuine religious devotion by composing in unpretentious verse (quatrains of monorhymed alexandrines, called *cauderna via*) lengthy lives

of saints (Saint Dominick of Silos, Saint Æmilianus, etc.), charming miracles of the Virgin ('Milagros de Nuestra Señora'), and kindred works. There is some reason to ascribe to him a voluminous account in *cuaderna via* of the deeds of Alexander the Great ('Libro de Alexandre'), which is otherwise anonymous. Anonymous as yet is a poem ('Libro de Apolonio') on the adventurous career of Apollonius of Tyre. Verse documents of less importance and also of the 13th century include a narrative dealing with the Legend of the Good Thief (but improperly called in the manuscripts the 'Book of the Three Kings of the East'), a Life of Saint Mary of Egypt ('Vida de Santa Maria Egipciaqua'), a Debate between Body and Soul, and a Debate between Water and Wine, with which is combined the oldest love song in the language. An adherence to Gallic sources and models is certain for some if not all of these documents.

It was chiefly through the efforts of Alphonsus X (reigned 1252-84) that Spanish prose composition received its first development. This learned sovereign made his court a centre for scientific and literary activity, and with the co-operation of the scholars whom he gathered about him he produced important astronomical, legal and historical compilations. It is a noteworthy fact that the king himself gave particular attention to the style of the documents thus compiled. Chief among them are the astronomical tables known since as the Alphonsine Tables; a comprehensive legal digest accompanied by a philosophical and interpretative commentary, the famous 'Siete Partidas'; and the 'Crónica General' (or 'Crónica de España') cited above. Following the fashion of the day he wrote his lyric verse in the language of Galicia, a form of Portuguese. After the close of the reign of Alphonsus and before the end of the century appeared the 'Gran Conquista de Ultramar,' which derives in part from William of Tyre's Latin history of Godfrey of Bouillon's crusade and in part from French and Provençal material of a romantic and novelistic nature. Very soon original prose fiction in Spanish became an actuality with the work entitled the 'Caballero Cifar,' and in the first half of the 14th century the short story was consciously and carefully elaborated in the framework of tales due to a prince of the royal blood, Juan Manuel (1282-1348), a nephew of Alphonsus X. Inspired by the labors of his uncle, whom he admired greatly, the warrior and statesman Juan Manuel found time not only for the composition of the 50 tales in his 'Conde Lucanor,' but also for that of much didactic material. Not the least interesting among prose writings of the 13th and 14th centuries are certain Spanish versions of sententious material taken from Arabic; from them seems to date the later widespread use of the proverb by the Spaniard.

The first genuine poet — the verse hitherto produced is not of a transcendent quality — comes to view in the person of the wayward cleric, Juan Ruiz, archpriest of Hita, in the first half of the 14th century. Even in the prison to which he was properly condemned for his misdeeds he continued to write lyrics of a spontaneous and self-revelatory sort. He collected them into what he termed capriciously

his 'Book of Good Love' ('Libro de Buen Amor'). While he narrates some of his own scabrous love affairs, he also displays his knowledge of Ovidian material and some acquaintance with French works, and he imitates a form of the popular lyric in his mountain-girl songs. The leading work in verse in the latter half of the 14th century is the 'Rimado de Palacio' of Pedro López de Ayala, a versatile man, who became Grand Chancellor of Castile. He served under four kings, and reveals his knowledge of affairs in his prose chronicle of their reigns, a work which is one of links in the series of chronicles stretching from 'Crónica General' of Alphonsus X down to the appearance of fully elaborated historical works in the age of the Renaissance. The 'Rimado de Palacio' is largely satirical in its constitution, inveighing against the vices and defects in all forms of society of his time.

During the long reign of Juan II of Castile, which nearly coincides with the first half of the 15th century, the court was thronged with versifiers whose methods were principally an imitation of those of the Provençal troubadours. These had been welcome visitors in Spain for a couple of centuries before and their themes had been acceptable to high society, especially their theorizing on love. But the re-echoes of their speculation that we find in the ditties of the Spanish poetasters of the 15th century are in the main stale and unprofitable, as may be seen in a survey of the examples contained in the collection ('Cancionero de Baena') made by the court physician and versifier, Juan Baena. In Aragon the Provençalizing methods also had vogue and they passed over to Italy with the establishment of an Aragonese court at Naples; some of the Spanish compositions written in Italy are assembled in the so-called 'Cancionero de Stúñiga.' At the Castilian court an allegorizing tendency, harking back above all to Dante and Boccaccio, was very marked, and the first notes of the coming Renaissance were struck when versions were made of some of the works of classic Latin. Enrique de Villena, an eastern Spaniard, related to the royal houses of both Aragon and Castile, was in no few respects an early Spanish humanist. The Castilian Íñigo López de Mendoza, Marqués de Santillana, was one of the more truly inspired writers of the time; he shows some appreciation of the popular poetry of his own land, along with an impress of Italian influences; and he used the allegorical forms with somewhat more felicity than most of his contemporaries. The most elaborate employment of allegorical machinery was made by Juan de Mena, court historiographer of Juan II, as may be perceived in his poem 'El Laberinto,' which also evidences the Spaniard's interest in the humanistic movement now spreading out from Italy.

While with austerity the inevitableness of death is preached in the stanzas of the Castilian 'Dance of Death' ('Danza de la Muerte'), a different view of the perishability of all things mortal is taken by the true poet Jorge Manrique (1440-78) in his sweet and mournful 'Coplas,' in which he declares that this mortal existence is but the threshold leading to the real life beyond the grave; gentle resignation is his key-note. From the pen of Gómez Manrique, the uncle of Jorge, now comes the first

plays in Spanish known to have been committed to writing since the appearance of the 12th century mystery play, and they are rather elementary in their make-up. Prose is used for satirical purposes with no little harsh effect by Martínez de Toledo, archpriest of Talavera, in his violent attack on woman, the 'Corbacho.' For historical purposes it is employed worthily by Fernán Pérez de Guzmán, whose character portraits in his 'Generaciones y Semblanzas' merit a place of distinction.

The Spanish ballad is one of the most prized manifestations of the national literary spirit. Naturally the earliest of those preserved in print could not precede the setting-up of the press, which appears to have occurred about 1474; only very few have been handed down from antiquity in manuscript form and none of these can antedate the 15th century. The oldest extant among the more than 2,000 ballads are heroic in subject, acclaiming the national heroes whom we have seen figuring in the Old Spanish epics and in accounts embalmed in the 'Crónica General.' According to an ingenious theory advocated by some leading Spanish scholars the most ancient among the ballads were simply portions of still older epics about the heroes, the parts of these latter that the people demanded most insistently from the popular entertainers, the *juglares*, who chanted and recited them; and the later ballads were modeled on these brief extracts. It has not been demonstrated, however, that ballads, that is, brief epico-lyric narratives, did not exist even as early as the very time of the heroic personages whom those known to us commemorate; such may have been the fact and they may have been kept alive by oral tradition until finally the first broadsheets were turned off from the press in the 15th century. At all events the Spanish ballad lives on with undiminished vitality; from the 16th century trained writers have imitated their form, and wherever people of the Spanish stock are found to-day new ballads are being produced by them. Certainly one of the most important works issued from the press before the end of the 15th century was the first discoverable edition of the famous chivalric romance, 'Amadís de Gaula,' the parent of a numerous progeny of Amadis, Palmerines and other stories of derring-do that were to keep on appearing down to the beginning of the 17th century, when the 'Don Quijote' was to give them their quietus. In some form or other the 'Amadís de Gaula' was already in circulation back in the 14th century, for there are references to it in other works of that period. Another noted novel, one actuated by a spirit which we now call naturalistic, was printed at least as early as the opening of the 16th century. This was the 'Celestina' or 'Tragicomedia de Calisto y Melibea,' which is strictly speaking an example of prose fiction in dramatic form.

Golden Age.—Under Charles V Spain attained to the proportions of a world empire, and a glorious development in literature as well as the other arts attended her great growth in political importance. During the preceding reign of Ferdinand and Isabella there were already clear signs of the inauguration of that period of literary splendor, which the Spaniards

term their *siglo de oro*, for a large measure of the humanistic culture of Italy had been transmitted to the Iberian Peninsula in the time of the Catholic sovereigns. In poetry a direct influence of Italian literature manifested itself ere the 16th century had proceeded far in its course, for through the efforts particularly of Juan Boscán (d. 1542) and Garcilaso de la Vega (1503-36) the various forms utilized by the Italians were imported into Spanish, and the old prosody was enriched by the addition of the 11 syllabled line, the octave, the sonnet, the ode, etc. The labors of these two poets in Spain paralleled in permanent effect those of the Pléiade in France and of Wyatt and Surrey in England. Other writers such as Diego Hurtado de Mendoza, Acuña and Cetina helped to acclimate the new forms and prevailed over more conservative spirits like Castillejo who resisted the innovations.

The flourish of the drama was perhaps the most distinctive feature of the century and a half or more during which the Golden Age of Spanish letters was in full vigor. The patriarch of the Spanish theatre was Juan del Encina, who had already begun to write before the end of the 15th century and who, like numerous Spanish authors after him, spent some time in Italy. Service in the Spanish campaigns took these men to the land of the Renaissance, where they imbibed the spirit prevailing there. A nomadic soul, Torres Naharro, published at the Aragonese court of Naples, in 1517, a collection of plays in which prominence is given already to the punctilio (*pundonor*), a motive which was to be stressed to an extraordinary degree in the further development of the Spanish drama. Lope de Rueda (d. c. 1565) imitated Italian dramatists very directly in his longer pieces, but attained his real success in the composition of brief comic interludes (*pasos*) that brought upon the scene popular characters taken from the life of the time. Rueda was an actor and stage-manager as well as a writer; since his time the vogue of the short one-act play of humorous and occasionally farcical tendencies has never died out in Spain; it is the *género chico* of to-day. With the pieces of Juan de la Cueva (d. c. 1609) the historical drama was introduced and to a certain degree he anticipated also the *comedia de capa y espada* which Lope de Vega was to cultivate with wonderful skill. Cervantes (1547-1616) essayed with no meed of success the rôle of the playwright, although two of his longer plays, the 'Numancia' and the 'Trato de Argel,' are not negligible. But beyond all odds the dominating personality among all Spanish dramatists of the first half of the Golden Age was Lope de Vega (1562-1635), who, inheriting technical details of dramatic composition from his immediate predecessors, applied them with the unerring skill of a dramatic genius. After Lope and until the end of the Golden Age the pre-eminent playwright was Calderón (1600-81). Lope tried his hand at practically every possible form of the drama and reached the height of his fame with his elaboration of the comedy of character and manners (*comedia de capa y espada*); his fertility was prodigious, as he seems to have written no fewer than 1,500 pieces. Calderón was not so markedly successful with the play of

manners, but he charmed his contemporaries as he still pleases posterity with the lyricism that pervades his pieces. He is celebrated most of all for his perfecting of the allegorical and religious drama dealing especially with the virtues of the Eucharist (*auto sacramental*). Lope, it should not be forgotten, exercised his talents in many directions and left untried hardly any of the genres; he will always be classed among the best of Spanish lyric poets. Other dramatists of the *siglo de oro* of pronounced merit were Gabriel Téllez (pseudonym, Tirso de Molina; 1571-1648), Guillén de Castro (1569-1631), Ruiz de Alarcón (d. 1639), Rojas Zorrilla (d. 1660) and Moreto (1618-69).

The dramas of the Golden Age are regularly in verse. In prose the most distinguished achievements took form in the novel and the short story, and a consideration of these at once suggests the name of Cervantes (1547-1616). His 'Don Quijote' (First Part, 1605; Second Part, 1615), the most noted work of Spanish *belles-lettres* and the greatest novel in the history of the world's literature, was begun as a satire upon the methods of the novel of chivalry but remains important as one of the most eminent expositions of the never-ceasing struggle between realistic and idealistic impulses in human nature. His 'Exemplary Tales' ('*Novelas Ejemplares*') set up a model for the shorter form of prose fiction. Before the middle of the 16th century there had been printed the 'Lazarillo de Tormes,' the earliest of the picaresque stories or novels of roguery, which, if not the work of Hurtado de Mendoza, must remain anonymous. Later novels of the type, recounting the wanderings and exploits of a roguish hero, are the 'Guzmán de Alfarache' of Mato Alemán (d. 1609), the 'Pícara Justina' (1605), of Úbeda, the 'Buscón' of the publicist and satirist Quevedo, and the 'Marcos de Obregón' of Vicente Espinel (1618). After Cervantes the short story was cultivated with some understanding by Salas Barbadillo, Castillo Solórzano and María de Zayas. The pastoral romance was attempted by many writers, even Cervantes and Lope de Vega being of the number, but the highest measure of success in the genre was achieved by Jorge de Montemayor in his 'Diana' (c. 1558), and by Gil Polo in his sequel thereto. A solitary but not infelicitous example of the historical novel in the age is the 'Guerras Civiles de Granada' of Pérez de Hita. True history writing takes the place of the earlier chronicles at this time, above all in the 'Historia de España' (written originally in Latin) of the Jesuit Mariana (d. 1623), in the accounts of affairs in eastern Spain by Zurita, and in the records of happenings in the New World by Antonio de Solís (d. 1688), and many others. History was intentionally mingled with fiction by Antonio de Guevara (d. 1545) in his 'Marco Aurelio' and his 'Década de los Césares,' and to him is due also the 'Epístolas Familiares,' a work which in translation eventually reached England and is said to have helped to promote an over-refined style of composition there. At least a mention should be made of the prose labors of the religious of the period who wrote many documents of a mystical, devotional and purely theological sort. Prominent among the mystics were Saint Theresa (1515-82), Saint John of

the Cross (d. 1591), Luis de Granada (d. 1588) and Luis de León (1527-91). The last named is one of the most attractive of all Spanish lyric poets, and shows his mystical bent in his verse no less than in his prose. Other lyric poets of high rank are Herrera (1534-97) and Rioja (d. 1659). The epic was essayed after the fashion of the Italians Ariosto and Tasso by many authors, including Lope de Vega and Barahona de Soto, but the only truly meritorious performance of the kind is the 'Araucana' of Alonso de Ercilla (1533-94), dealing with campaigns against the Indians in South America in which he played a part.

Even at the moment of greatest efflorescence the seeds of ultimate decay were sown in Spanish literature, and chiefly by the poet Luis de Góngora (1561-1627), who deliberately engaged in the use of stylistic excesses of many sorts, such as intentional obscurity of expression, and the like. He was unfortunately taken as a desirable model by even the most famous writers and hence the spread of the manner called Gongorism (also culteranism or cultism), which, as the 17th century wore on, it was deemed absolutely necessary for writers to employ in both prose and verse. While Gongorism played with the external form, of literature, gradually debasing it, there were other mannerists who purposely juggled with the philosophic idea of concept, and thus added a sinister influence. The methods of the Conceptists may be judged by the works, which are nevertheless of substantial merit in certain regards, of the Jesuit Gracián (1601-58).

The 18th Century.—After the death of Calderón (1681) it may be said that a period of decay set in rapidly in the field of letters; it became well-nigh absolute in the early years of the 18th century. The writers were still many but their aesthetic sense and that of their readers were of a deplorably low order. The advent of the Bourbons with Phillip V, who came to the throne in 1700, led to a large influx of Frenchmen to the court and a considerable Frenchifying of fashions. From France there came also the neo-classic methods of her writers, which the critic Ignacio de Luzán (1702-54) recommended to his Spanish fellow-countrymen as providing a panacea for the literary ills of Spain. In his 'Poética' (1737) Luzán paid particular attention to the reform of the Spanish theatre which had fallen into a chaotic condition and he urged the adoption by Spanish playwrights of the three unities and the other leading principles of neo-classic restraint which had been in force in France since the 17th century. The ideas of Luzán met with acceptance; there was some translation of French dramatic pieces and some Spaniards of talent wrote original plays cast in the French classic mold. Among these were N. F. de Moratín (Moratín the Elder, 1737-80), the statesman Jovellanos (d. 1811), and Moratín, the son (Leandro Fernández de Moratín, 1760-1828). The greatest of the trio was the last named, who acquired favor with the many by means of his pieces reflecting his veneration for the French dramatist Molière; and especially by his two prose plays, 'El Café' and 'El Si de las Niñas.' A school of poets who gathered about Meléndez Valdés, a professor at the University of Salamanca, sought

to subordinate lyric composition to the same principles of neo-classic restraint and, though they succeeded in attaining to some plasticity of form, they did so to the detriment of emotional expression. In the domain of the versified fable a high degree of excellence was reached by Iriarte (1759-91) and Samaniego (1745-81), who were familiar with the work of La Fontaine and of other foreign fabulists as well. With a satirical novel, the 'Fray Gerundio' (1758), the Jesuit Isla gained much éclat and also contrived to bring about a reform of the sensational methods of preachers of his day. Isla won notice, furthermore, by his Spanish translation of the 'Gil Blas' of the French novelist Lesage, which, in accordance with a false assertion of Voltaire, he regarded as a plagiarism of a lost Spanish picaresque romance. The scientific discoveries of the outside world were communicated to his countrymen by the Benedictine Feijoo (1726-1829) through the medium of the essays contained in his 'Teatro crítico' and his 'Cartas eruditas y curiosas.' The cultured soldier José de Cadalso (1741-82) repeated in his 'Cartas Marruecas' the satirical methods utilized by Montesquieu, in his 'Lettres persanes,' and derived inspiration for his 'Noches lúgubres' from Young's 'Night Thoughts.' Ramón de la Cruz (1731-94) showed the universal predilection for things Gallic in his adaptations of French plays, but he took a unique stand for the age when he produced his *sainetes* of an entirely native flavor, for they are one-act pieces reproducing the methods of the old *paseo*. Sarmineto, Hervás and Arteaga are notable among the historians, scholars and critics of the period.

The More Recent Period.—Only to a slight degree did the rationalistic spirit of the French 18th century show itself in the workings of the minds of the French writers who have been mentioned thus far as subordinating themselves to the precepts of neo-classicism. But in the leading author of the opening of the 19th century rationalism dominates along with fiery liberalism. He is Quintana (1772-1857). His enduring fame, however, rests more upon the heroic odes in which he, a patriotic Spaniard, assailed the Napoleonic invaders of his land during the War of Independence. With him was associated the priest Gallego (1777-1853), who wrote patriotic odes and elegies of highly plastic form. Though they fought the Frenchman as the enemy of their country, Quintana and Gallego did not disclaim the methods of neo-classicism. These methods still found acceptance with the young men who constituted the coterie of writers known as the School of Seville, but in the poetry of the guiding spirits among them, such men as Arjona, Lista, Blanco and Reinoso, there is also evident a respect for the older and purely Spanish literary tradition.

The Romantic movement which had swept Europe outside reached Spain somewhat belated in the fourth decade of the century. Liberal writers who had fled the land during the despotic rule of Ferdinand VII returned at his death in 1833 and helped efficaciously in spreading the evangel of Romanticism which had come to them in England and France. As understood by them Romanticism was the very

antithesis of Classicism, in that it threw off all restraint and believed in giving unchecked expression to the feelings of the inner man, and, moreover, it sought inspiration in the Christian Middle Ages and not in pagan classic antiquity so favored by the classicists. Martínez de la Rosa (1787-1862), who is in many respects still a votary of Classicism, manifested clear tendencies toward Romanticism in his play 'La Conjunción de Venecia' (1834). A decided victory for the new doctrines was won in 1835 by the performance at Madrid of the play 'Don Alvaro' by the Duque de Rivas (1791-1865), who likewise introduced the Romantic spirit into the lyric with his 'Faro de Malta,' and into narrative poetry with his 'Moro Expósito.' The fervor of Romantic enthusiasm is patent in one of the most transcendently lyrical of all Spanish poets, José de Espronceda (1809-42), who rose up rebellious to all social and literary convention and proved to be an apt, though not a servile, disciple of Byron, in his longer compositions, the 'Estudiante de Salamanca' and the 'Diablo Mundo.' The Romantic's love for mediæval traditions has full expression in the legends in verse of José Zorrilla (1817-93), who has, besides, achieved widespread popularity with his drama 'Don Juan Tenorio.' The Romantic ferment appears but slightly in the pieces of the prolific playwright, Bretón de los Herreros (1796-1873), who delighted rather in rendering pictures of living manners. The poetess and dramatist, Gertrudis de Avellaneda (1814-73) alternated Romantic and Classic moods. By the middle of the 19th century the realistic attitude prevailed over the Romantic and has done so ever since both on the boards and in prose fiction. The dramatists López de Ayala (1829-79) and Tamayo y Baus (1829-98) pictured vividly the corruption of manners induced by the exaggerated materialism and positivism of society and the business world. While the historical drama has a brilliant representative in the 'Haz de Lefía' of Núñez de Arce (1834-1903), the theatre of recent times has not been marked by the appearance of works of great and lasting merit. At the moment, the *género chico* (one-act plays frequently farcical of plot) holds sway; still a really artistic endeavor is revealed in the more ambitious plays of Benavente and the Quintero brothers. Much praise can hardly be accorded to the dramatic attempts of the essentially novelistic genius, Pérez Galdós.

The splendid development given to the novel is the boast of the Spaniard of to-day. Out of essays on local manners as written by Larra, Miñano, Mesonero Romanos and Estébanez has grown the regional novel which portrays the life of southern Spain in the works of Fernán Caballero (Cecilia Böhl de Faber, 1796-1877), that of the north and of the capital in the stories of Pereda (1834-95), that of eastern Spain in the novels, often tracts, of Blasco Ibáñez, that of her Galicia in the fiction of the Countess Pardo Bazán (b. 1851), that of various places in the narratives of Palacio Valdés, and that of the whole land in the many psychological novels of Pérez Galdós. The last named has also cultivated the historical novel with extraordinary skill through four series of stories, each containing 10 novels, which cover the course of national events from

the reign of Carlos IV down through the midpoint of the 19th century. Somewhat of the naturalism of Zola and the de Goncourt brothers is visible in the productions of one or another of these authors, but it is not usually carried to morbid extremes. Juan Valera (1824-95) can hardly be associated with the realistic novelists, and yet he is not an idealist; his geniality and sprightly fancy have won him many admirers. The number of the other writers of prose fiction that might be mentioned is simply legion. Perforce mention of them is omitted here, as also of the many prose writers who have gained well-merited praise for their historical and critical labors. Nevertheless, record must be made of the highly cultured and acute literary critic, the late Menéndez y Pelayo, and of the brilliant philologist, Menéndez Pidal. Notable among the lyricists since the middle of the 19th century are Bécquer (1837-70), whose beautiful poems are often pure music, and the cynically but not unpleasantly pessimistic Campoamor. Lyric verse and novels are constantly appearing in undiminished profusion. The events of the World War have provided scope for the imagination of Blasco Ibáñez in his 'Cuatro Jinetes del Apocalipsis' and his 'Mare Nostrum.' See *AMADIS DE GAULA*; *CELESTINA*, *THE*; *DON QUIXOTE*; *POEM OF THE CID*.

Bibliography.—Fitzmaurice-Kelly, 'History of Spanish Literature' (best consulted in the second Spanish edition: it has a copious bibliography); Ticknor, 'History of Spanish Literature' (antiquated in part, but useful for its analyses of masterpieces; it does not treat of the greater part of the 19th century); Menéndez y Pelayo, 'Antología de Poetas Líricos Castellanos' (this treats of the history of Spanish poetry from the earliest times down to the Golden Age in the introductions to its various volumes); Cueto, 'La Literatura Española del Siglo XVIII'; Blanco García, 'La Literatura Española en el Siglo XIX'; Ford, 'Main Currents of Spanish Literature.'

Smith Professor French and Spanish Languages, Harvard University.

SPANISH MACKEREL, a mackerel (*Scomberomorus maculatus*), with the body more compressed than that of the common mackerel and the head short and conical. It reaches a length of about 30 inches and is a handsome fish marked on the sides with round golden bronze spots which distinguish it at once from any other fish occurring in our waters. This mackerel is properly a tropical species, but during the summer migrates northward along the Atlantic Coast, occasionally reaching Cape Cod. It is one of the most graceful and active of fishes, and swims at the surface in schools in pursuit of menhaden, silversides and other smaller fishes, which constitute its chief diet. The species is very prolific, each female producing from 300,000 to 1,000,000 of the small buoyant eggs which develop rapidly and may hatch within a single day. In Chesapeake Bay, which is an important spawning ground, the breeding season is June. A favorite game-fish in the south, the Spanish mackerel is commercially of considerable importance, being excellent for table use. It was very little known before the introduc-

tion of the pound-net into our fisheries. Many mackerel are taken in these nets about Sandy Hook, but the most important fisheries are in Chesapeake Bay, where gill-nets are also employed largely in their capture. The sierra (*S. regalis*) and the silver cero or king-fish (*S. cavalla*) are related species found in the West Indies and along the coast of the South Atlantic States. Several fish found in southern waters are known as Spanish mackerel, the species to which the name is applied varying with the locality.

SPANISH MAIN, a name formerly given to the coasts of the Spanish colonies bordering on the Caribbean Sea, and often transferred to the sea itself. In the latter sense it occurs frequently in connection with the buccaneers. See *BUCCANEERS*.

SPANISH MOSS, an epiphytic, pendulous plant (*Tillandsia usneoides*) of the pineapple family, which is widely distributed throughout tropical America. The soft-hair seeds are carried by the wind to the rough bark of tree-branches, where they lodge and germinate. The stems are very slender, gray and scurfy, sometimes several feet long, bear scattered leaves which are narrowly linear and have in their axils solitary, regular and perfect three-parted flowers, which are yellow-petaled but inconspicuous. The plants are silvery gray in tone, which accounts for their common name of old man's beard; and they drape the forests extensively and mournfully, in contrast with the evergreen of pines and live oaks, as far north as the Carolina Coast. They are used after drying as packing for articles in boxes, stuffing for cheap mattresses, etc. See *FIBRE*.

SPANISH MUSIC. Spanish art and literature are characterized by the short duration of their flowering season. Two centuries—from 1500 to 1700—include almost everything that is eminently important in these fields. Calderon, Lope de Vega, Cervantes, Velasquez and Murillo,—all belong to this period. It is also the period of Spanish eminence in music. Indeed, were it not for the fact that most of the composers who lived at this time developed their activities in Rome instead of their native country, we might even speak of a distinct Spanish school. As it is, the composers in question formed an integral part of what is known as the Roman school of church music,—culminating in the renowned Palestrina. The most important masters of Spanish origin connected with this school were Morales and Vittoria, both living in the 16th century. The former, a writer of great seriousness and elevation of style, was a predecessor of Palestrina in the Papal chapel and probably exercised considerable influence on his musical development. The latter was one of the most prominent successors of the great Roman composer. Indeed, the names of the two are often linked together, just as the men were intimate friends during their lifetime. Though not quite the equal of Palestrina in technical mastery and variety of expression, Vittoria has certain qualities of emotional depth and tenderness which are distinctively his own. Other eminent composers of early church music were Escobedo and Guerrero. Since the time of these masters there has been a decline in the cultivation of the musical art, and Spanish

composers have taken but little part in the wonderful developments of opera and instrumental music of the last three centuries. However, their country has given the world some of its greatest teachers and reproductive artists, such as Garcia, Malibran, Sarasate and Patti. And in recent years there has been renewed activity in the field of composition which augurs well for the future.

It is to Spain that we owe two instruments which, though not of paramount importance, occupy a characteristic place in the family of musical mechanisms. We refer to the guitar and castanets. And it is to Spain, likewise, that we are indebted for some of the most characteristic dances in existence. Among these we may mention the fandango, bolero, cachucha, jota and seguidilla. The celebrity of these dances is justly deserved, for they are highly picturesque both by reason of the general appearance of the participants and on account of the unique nature of their movements, which are full of grace and animation. The accompanying music is generally in triple time and is likewise characteristic, especially in its rhythm. Indeed, the Spanish dance has now settled into a distinct type of composition and is considerably used by composers as a vehicle of expression. We need but refer, in this connection, to Moszkowski's celebrated dances. All in all, the Spanish dance may be regarded as the most important contribution which has been made by the Iberian Peninsula to the music of to-day.

ALBERT GEHRING.

SPANISH PEAKS, two isolated mountains which form prominent landmarks in southern Colorado, near the Mexican border. The summit of the higher peak is 13,623 feet above sea-level. It is partly composed of volcanic rocks. The other mountain is 12,720 feet high.

SPANISH REFORMED CHURCH, a church organization founded in Spain in 1869. The movement originated with the native Spaniards, but was assisted by English and Irish Episcopalians, who in 1867 founded the Spanish and Portuguese Church Aid Society. The church of the Redeemer was established at Madrid under its auspices in 1869, and later 10 other churches were established under the name of the Spanish Reformed Church. The first bishop of the church was Juan Bautista Cabrera, who was consecrated to his office by the archbishop of Dublin in 1887. There are now more than 20 congregations, of which the most important are those at Madrid, Valladolid, Salamanca, Malaga and Seville. The Church is governed by a synod composed of both the clergy and of laymen. Its doctrines follow those of the established creeds with perhaps the greatest similarity to the Episcopal Church.

SPANISH SUCCESSION, War of the. See SUCCESSION WARS.

SPANISH TOWN, or **SANTIAGO DE LA VEGA**, town in Jamaica, on the Cobre River, 10 miles west of Kingston, with which it is connected by railroad. It is the second town in importance on the island; was founded by Diego Columbus in 1525 and was formerly the capital; but the seat of government was moved to Kingston in 1871. Pop. about 8,500.

SPANISH WAR VETERANS, a society organized by men who took part in the Spanish-American War. The object of the society, which was incorporated 28 Nov. 1899, is to keep alive the memories of the war with Spain in a patriotic American sense and not with the view of nursing any feeling of international enmity, to promote the best interests of those who took part in the war in the service of the United States and to encourage universal liberty and equal rights and justice. Although the number of killed and wounded in the Spanish War was not large, as compared with other wars in which the United States has been engaged, the character of climate and the season of the Cuban campaign were such as to do permanent injury to thousands of veterans not wounded in battle, while many suffered serious detriment to health who never passed beyond the Southern camps. This society was united in 1904 with the Society of Spanish American War Veterans, the Society of the Service Men of the Spanish War and the Society of the Hispano-American War, and is known as the "United Spanish War Veterans." It concerns itself with the interests also of those who participated in the Philippine campaign and the Chinese Expedition.

SPANISH WAR VETERANS, National Auxiliary of, an association composed of the mothers, wives, sisters and daughters of members of the Society of Spanish War Veterans, also of other women, such as nurses, who rendered special service during the war in camp or hospital or otherwise.

SPAR, a general name in mineralogy for a crystalline mineral which is not an ore easily cleavable. Thus we have feldspar, comprising both orthoclase and plagioclase; calcspar or cleavable calcite, with its transparent variety iceland spar; fluor spar or fluorite; satin spar, or fibrous gypsum; tabular spar, or Wollastonite and heavy spar or barite. The term is of German origin.

SPARGO, John, American author: b. Stithians, Cornwall, England, 31 Jan. 1876. He was educated in the public schools and under the University extension courses of Oxford and Cambridge. At the age of 18 he became identified with the Socialist movement in England; he publicly opposed the Boer War and in 1901 came to the United States, where he has been active as Socialist lecturer, writer and worker. In 1910 Mr. Spargo was United States delegate to the International Socialist and Trade Union Congress, Copenhagen. For several years he served on the national executive committee of the Socialist party; was delegate to all leading conventions of the party; and State chairman of Vermont. In May 1917 soon after the entry of America in the war with Germany, Mr. Spargo resigned from the party because of its unpatriotic attitude toward the war. In 1918 he was made temporary chairman of the National Socialist party organized along new lines that year and became director of propaganda and of educational activities in the new party. Mr. Spargo is a founder of Prospect House Social Settlement, Yonkers, N. Y., and is a member of the New York Milk Commission and of other philanthropic societies. He has published 'The Bitter Cry of the Children' (1906); 'Socialism, a

Study and Interpretation of Socialist Principles' (1906; rev. ed. 1909); 'The Socialists, Who They Are and What They Stand For' (1906); 'Underfed School Children' (1906); 'Forces that Make for Socialism in America' (1906); 'Capitalist and Laborer' (1907); 'Not Guilty,' a drama (1907); 'The Common Sense of the Milk Question' (Japanese and other translations 1908); 'The Common Sense of Socialism' (1908); 'The Socialism of William Morris' (1908); 'The Spiritual Significance of Modern Socialism' (1908); 'Socialist Readings for Children' (1909); 'The Substance of Socialism' (also Armenian and other translations, 1909); 'Karl Marx, His Life and Work' (1909); 'The Marx He Knew' (1909); 'Side-lights on Contemporary Socialism' (1910); 'Elements of Socialism,' with Professor Arner (1911); 'Applied Socialism' (1912); 'Syndicalism, Industrial Unionism and Socialism' (1913; various translations); 'Socialism and Motherhood' (1914); 'Marxian Socialism and Religion' (1915); 'Socialism and Internationalism' (1917); also numerous pamphlets, brochures and magazine articles on social and economic questions and art. With Samuel Gompers he founded the American Alliance for Labor and Democracy in September 1917.

SPARIDÆ, a large family of carnivorous shore-fishes, the porgies, of tropical seas, especially abundant in the Mediterranean, Red Sea and West Indian waters. None is of great size. The body is oblong, likely to be elevated, covered with large adherent scales and ornamental colors; the mouth is filled with strong teeth, in which the incisors are prominent. Most of them are excellent food and many are gamy. Jordan says that about 11 genera and 100 species are counted in the family, about half of which occur in North American waters. These include the scup, porgies, sheepshead and related fishes. Consult Goode, 'American Fishes' (New York 1888); Jordan and Evermann, 'Fishes of North and Middle America' (Washington 1898).

SPARKLING WINE. See WINE AND WINE MAKING.

SPARKS, Edwin Erle, college president and American historical writer: b. Licking County, Ohio, 1860. He was graduated from the Ohio State University in 1884 and from the University of Chicago in 1900. He was instructor at Ohio State University 1884-85; professor at Pennsylvania State College 1890-95; lecturer before the American Society of University Extension 1893-95; professor of American history at the University of Chicago from 1895 to 1908; and since that date president of the Pennsylvania State College. He has published 'Expansion of the American People' (1899); 'The Men Who Made the Nation' (1900); 'Formative Incidents in American Diplomacy' (1902); 'The United States' in the 'Story of the Nations Series' (1903); 'Foundations of National Development' (1907); 'The Lincoln-Douglas Debates' (1908); and many contributions on educational administration subjects.

SPARKS, Jared, American scholar and historian: b. Willington, Tolland County, Conn., 10 May 1789; d. Cambridge, Mass., 14 March 1866. He was graduated from Harvard in 1815, studied theology with Dr. Nathaniel Thayer

from May 1817 to March 1818, was editor of the *North American Review*, then begun in Boston, and in 1818 entered the Unitarian ministry. On May 1819 he was ordained pastor of the Unitarian congregation at Baltimore, Md., Dr. W. E. Channing (q.v.) preaching on that occasion the well-known discourse of 'Unitarian Christianity.' Sparks did much in Baltimore to promote the growth of the Unitarian faith, instituting there a Unitarian book society and editing the *Unitarian Miscellany*, a monthly periodical. He resigned in 1823 and from 1823 to 1830 was again editor of the *North American Review*, in which he acquired a three-quarter interest. After some periodical contributions to the economic history of the South, and to Mexican and South American history, he published in 1828 a 'Life of Ledyard,' the American traveler. In the preparation of this work he first undertook that method of travel and research among original sources in which he was the pioneer in the United States and which he afterward so worthily applied to the study of American history. After long investigation, including a very wide correspondence and a voyage to Europe for the examination of records in the public offices of London and Paris, he published the well-known 'Writings of George Washington, with a Life of the Author, Notes and Illustrations' (1834-37), which remained the standard until partially superseded by W. C. Ford's edition (1889-93). Sparks used the copies of Washington's letters as found in the latter's letter-book. The discrepancies found to exist between the copies and the originals as preserved refuted the charges at first made to the effect that Sparks had wilfully altered the letters. Sparks' method of editing in general has, however, been discarded. He printed only what he believed of importance, omitting and altering passages as he saw fit. This was largely due to the idea of editorial discretion then observed, and should not be made occasion for disparagement. Whatever may be said of his methods in editing text, Sparks was a really distinguished historical scholar and maintained almost invariable as high a level of excellence as was then possible to the historical editor. He also prepared 'The Works of Benjamin Franklin' (1836-40); 'The Library of American Biography' (1st series 1834-38; 2d 1844-48), himself writing seven of the 60 lives; and 'Correspondence of the American Revolution' (1854). He also wrote 'Remarks on American History' (1837). He was professor of history at Harvard in 1839-49, and president in 1849-53. The standard biography is Adams, H. B., 'Life and Writings of Jared Sparks' (Boston 1893); there is also one by Ellis (1869). Consult also Bassett, J. S., 'Jared Sparks' in 'The Middle Group of American Historians' (New York 1917).

SPARKS, Nev., city in Washoe County, on the Truckee River, three miles east of Reno, and on the Southern Pacific Railroad. It has important railroad shops and ranks as a railroad town. It is closely connected with Reno by car lines. There is a high school and a public library. Pop. 2,500.

SPARROW, the familiar name of many small birds of the finch family (*Fringillidae*), applied loosely to the representatives of a large and varied assemblage of genera. Generally

speaking, sparrows are moderate-sized members of the family which live mostly on or near the ground, whose bills are neither especially short and stout nor angulated in the gape, and which have the sexes similarly colored. About 10 genera and 40 species called sparrows belong to the North American faunas of which the following may be mentioned. The white-crowned sparrow (*Zonotrichia leucophrys*) is about seven inches long, the body stout, and the tail rather long and moderately rounded; the chin, throat and breast are nearly uniform ashy; the head above black; median and superciliary stripe pure white; a narrow black line through and behind the eyes; back and wing-coverts dark reddish brown with paler margins; quills and tail darker; wings with two white bands; whitish below; bill reddish orange tipped with brown. It is found from the Atlantic to the Rocky Mountains and from Labrador to Texas, breeding to the north and in the Rocky Mountains. The notes are mellow and sweet, six or seven in number, the first loud and clear, and then becoming fainter and more plaintive; eggs light green with brownish mottlings at the larger end. The nest is on the ground or among moss, and the eggs are laid in Labrador from the 1st to the end of June. The flight is low and swift; the migrations are performed mostly by day; the food consists of seeds, berries and insects. It spends its summers in northern Canada and Alaska. The white-throated sparrow or peabody bird (*Z. albicollis*) has the chin abruptly white; superciliary stripe broad, yellow anteriorly and white behind; median head-stripe white, with a black one on each side, and a broad black streak behind the eye; edge of wing and axillaries yellow; two narrow white bands across wing coverts. It is found in the eastern United States and westward to the Missouri, appearing in the Southern States in November and departing in March to the North. It breeds from the northern tier of States northward, and its nest, eggs and song resemble those of the last mentioned. This species is very active among hedges and thickets, and is found in flocks with the white-crowned sparrow, than which it is generally more plentiful. These, with two or three additional western species of *Zonotrichia*, are among the largest and most handsome of our sparrows.

The genus *Spizella*, which differs from the last in its smaller size and longer forked tail, contains three well-known northern species and as many more confined to the western and southern United States. The field sparrow (*S. pusilla*) is about five and one-half inches long; the bill is reddish; ear coverts, crown and back rufous, the last with blackish streaks; sides of head and neck, and stripe over eyes, ashy; white below, tinged with yellow anteriorly; quills and tail faintly edged with white, and two bands of the same across wing coverts; rump yellowish brown. It is found in eastern North America as far as the Missouri, remaining in the Southern States during winter, going north in March, and arriving in New England toward the last of April. The song is pleasing, resembling the trill of a young canary. It is sociable and peaceful, and very prolific, sometimes raising three broods a year. The nest is of grasses and placed on or near the ground; the eggs usually four or five, whitish, thickly

speckled with reddish brown. It frequents fields and fence rows, and flocks when not breeding. The chipping-sparrow (q.v.) and tree-sparrow belong here. The genus *Passerella* is remarkable for the elongation of the lateral toes and the large size of the claws, adapting these birds for scratching on the ground. The fox-colored sparrow (*P. iliaca*), with its several varieties, is our only representative. It is seven inches long, the back is rust brown, margined with ashy, lighter on the head, tail and wing coverts, rufous on the last two; white below, streaked with light brownish red on breast and sides of neck, rufous patch on cheeks. It is found as far west as the Mississippi, preferring the Northern States and going south in winter. It is seen in small flocks in the underwood and along brier-skirted fences and streams. It breeds in British America. The flight is slow, rapid and undulating; the song clear, full, sweet and prolonged with many repetitions. The nest is made on the ground or in bushes.

Other important genera are *Ammodramus*, with 11 species, including the savanna sparrow (*A. sandwichensis*), the yellow-winged grasshopper sparrow (*A. passerinus*), the sharp-tailed sparrow (*A. caudacutus*), and the seaside sparrow (*A. maritimus*), the last two inhabitants of salt marshes, *Melospiza*, including the song sparrows (q.v.); *Poocates*, with the vesper sparrow or bay-winged bunting (*P. gramineus*); and others less well-known. The sparrows of Europe are few in number and belong to the genus *Passer*. Besides the house sparrow, the European tree-sparrow (*P. montanus*) has been introduced into this country. There is also an American bird of the same name, also called Canada sparrow (*Spizella monticola*), which much resembles the chipping-sparrow, but has a distinct dark spot on the breast and conspicuous white wing-bars. It is a northern bird, but in the winter is abundant in the United States, flocking in fields and shrubbery.

Consult: Ridgway, 'Birds of North and Middle America,' Part I. (Washington 1902); Forbush, 'Useful Birds and Their Protection' issued by the Massachusetts Board of Agriculture (1913); and general works on ornithology. For the "English" sparrow, see HOUSE-SPARROW.

SPARROW-HAWK, a small falcon (*Falco sparverius*), common throughout North America and practically cosmopolitan, since scarcely distinguishable species inhabit all quarters of the globe. It is 11 to 12 inches long, and the adult male has the back tawny; wings bluish and black; seven black blotches about the head; tail chestnut, with a broad black band and a narrow terminal one of white; below white or tawny. The female is more streaky, has the tail tawny with numerous narrow, darker bars; back and wing-coverts rusty, barred with black. These birds are true falcons (see FALCONRY), and admirably bold and active. Not infrequently the sparrow-hawk may be seen to attack other and larger birds of prey, its courage extending even to recklessness, while it is also shy and wary. It feeds largely on mice, which it catches with great skill, and also sometimes seizes young chickens, but its depredations in that direction are of little consequence. It

makes its nest in hollows of trees, the deserted hole of a large woodpecker, or sometimes an abandoned crow's-nest.

SPARROW-OWL, one of the diminutive, brown-streaked owls of the genus *Nyctale*, of which the saw-whet (q.v.) is a familiar example. The name belongs primarily to Tengmalm's owl of Northern Europe, of which Richardson's own (*N. richardsoni*) of Canada and Alaska is an American variety. It is bold and strong, and feeds mainly on small birds.

SPARTA, spär'ta, a celebrated city of ancient Greece, the capital of Laconia and of the Spartan state, was situated on the west bank of the river Eurotas, and embraced a circuit of six miles. Sparta was irregularly built, and from this circumstance it is supposed to have got its name, signifying "scattered." It consisted of five separate quarters, which were not completely surrounded by walls till the time of the Romans. It was the boast of Sparta that her men were her walls. Among other remarkable objects enumerated by Pausanias are the following: the market-place, containing the public buildings, in which the council of the elders held their meetings, and the principal ornament of which was the Persice, a celebrated colonnade, built from the spoils taken from the Persians, its roof being supported by statues of Persians; the theatre, the remains of which constitute the principal ruins of Sparta; the Choros, or place in which the ephebi executed their dances, adorned with statues of Apollo, Artemis and Leto; the Leschai, or halls in which the popular assemblies were held, and of which there were two—the Lesche of the Crotanes, near the tombs of the Agides, and the Lesche Pœcile; the Temple of Athene Poliouchos or Chalkioikos (as the goddess was commonly called, from the bronze ornaments of her temple), on a steep hill, to which the Spartans gave the name of the Acropolis, etc. Sparta was the name of the city during the period of its historical celebrity. Lacedæmon is found in Homer as the name both of the city and the territory, but it afterward dropped out of use, and does not appear to have been revived till several centuries after Christ. Laconia, the district in which Sparta was situated, was the southeastern division of the Peloponnesus, bounded on the west by Messenia, from which it was separated by the chain of Taygetus, on the north by Arcadia and Argolis and on the east and south by the sea. The principal towns in Laconia besides Sparta were Amyclæ and Pharis, both situated like Sparta on the west bank of the Eurotas, a little lower down.

The Spartans were the descendants of the Dorians who invaded the Peloponnesus about 80 years after the siege of Troy, and from an early period they conformed to a set of rigorous institutions aimed at making them a purely warlike nation. These institutions they themselves ascribed to Lycurgus, who, if he was really a historical character, must have lived not later than the 9th century. It is probable that shortly after their settlement in the Peloponnesus the Spartans extended their sway over all the territory of Laconia, the inhabitants of which they reduced partly to the condition of Helots and partly to that of Periæci. The former were completely enslaved, bound to the land which they had to till for their

masters, and required to serve the state in war. The latter were free, possessing land of their own, and carrying on trade and practising the arts, both of which pursuits were forbidden to Spartans. The next great wars of Sparta are usually regarded as the direct consequence of their new institutions. They were waged with the Messenians in the 8th and 7th centuries B.C., and resulted in 668 B.C., in the complete subjugation of the Messenians, who were either compelled to leave their country or were reduced to the condition of Helots. Wars

were also carried on against their northern neighbors, the Arcadians and the Argives, against both of whom they were successful, and before the close of the 6th century B.C., they not only stood at the head of the states of the Peloponnesus, but were even recognized as the leading people in all Greece. Early in the following century began the Persian wars, in which Sparta played a conspicuous part, but the details down to the conclusion of the Peloponnesian War in 404 B.C. belong to the common history of Greece, to which the reader is referred. The events of the wars with Persia led to Sparta being supplanted by Athens as the leading state in Greece; hence arose a jealousy between the two cities which ultimately brought on a war, in which the one-half of Greece was divided against the other, and this war, the Peloponnesian, ended in the ascendancy of Sparta and the entire humiliation of her rival. The rivalry of the Spartan general Lysander and the king Pausanias soon after produced a revolution, which delivered the Athenians from the Spartan yoke (403). A little later the Spartans became involved in a war with Persia, by joining Cyrus the Younger in his rebellion against his brother Artaxerxes Mnemon (401). The war was continued even after the failure of the enterprise of Cyrus, and the Persian throne was shaken by the victories of Agesilaus; but Athens, Thebes, Corinth and some of the Peloponnesian states took this opportunity to declare war against the Lacedæmonians. The latter defeated the Thebans at Coronea (394); but, on the other hand, the Athenian commander Conon gained a victory over the Spartan fleet at Cnidus. This war, known as the Bœotian or Corinthian War, lasted eight years, and increased the reputation and power of Athens. To break the alliance of Athens with Persia, Sparta, in 387 B.C., concluded with the latter power the peace known by the name of Antalcidas; and the designs of Sparta became apparent when she occupied, without provocation, the city of Thebes, and introduced an aristocratical constitution there. Pelopidas delivered Thebes, and the celebrated Theban War (378-363) followed, in which Sparta was much enfeebled. During the following century Sparta steadily declined, although one or two isolated attempts were made to restore its former greatness. The principal of these was made by Cleomenes (236-222), but his endeavors failed, because there were then scarcely 700 of Spartan descent, and the majority of these were in a state of beggary. With the rest of Greece Sparta later passed under the dominion of the Romans in 146 B.C.

The Spartans differed from the other Greeks in manners, customs and the constitution of their state. Their kings (two of whom always reigned at once) ruled only through the popular

will, acting as umpires in disputes and commanding the army. The Spartans proper, that is, the descendants of the Dorians, occupying themselves with war and the chase, left all ordinary labor to the Helots, while the class known as Periœci engaged in commerce and manufactures.

SPARTA, Ill., city in Randolph County, 45 miles southeast of Saint Louis, on the Illinois Southern and the Mobile and Ohio railroads. There are coal mines in the vicinity, and industries include railroad repair shops and manufactures of plows and harrows, flour and planing-mill products. Pop. 3,081.

SPARTA, Wis., city, capital of Monroe County, on the La Crosse River, and on the Chicago, Milwaukee and Saint Paul and the Chicago and Northwestern railroads, about 23 miles northeast of La Crosse. It is a favorite summer resort. It is in an agricultural and fruit-growing region. It has flour and feed mills, machine shops, paper mills and cigar factories. The educational institutions are a high school, public and parish elementary schools, and a public library. The city contains several churches and the State School for Dependent Children, and the Hospital for the Insane is a short distance north. The three banks have a combined capital of \$100,000. Sparta was first settled in 1851, was incorporated as a village in 1857, and as a city in 1883. It is governed by a mayor and a council of eight, elected biennially. Pop. about 4,000.

SPARTACANS, or SPARTACIDES, is the name acquired soon after the going into effect of the armistice accorded Germany in Nov. 1918, by the special followers of Karl Liebknecht (q.v.), leader of the extreme left wing of the German Socialist party, or Independents, notably during the several risings of the latter against the moderate, or majority, Socialists under the leadership of Ebert and Scheidemann, who had formed a composite government from which the Spartacans had withdrawn as not realizing their political and economic ideals. There were several of these organized, or centralized, risings, the more considerable occurring in January 1919, when in Berlin alone the deaths in the fighting on both sides were computed at sundry thousands, and quite a number of local and insufficiently organized ones in various parts of Germany, such as Halle, Brunswick, Leipzig, Dresden, Hamburg, Bremen, Duisburg and other places. The communistic uprising in Munich, on the other hand, which occurred during March and April 1919, does not properly figure under the head of Spartacan undertakings. The name of "Spartacan" originated from the pen name of Karl Liebknecht, "Spartacus," which he had adopted while being held prisoner by the former German imperial government during the last two years of the Great War, 1916-18, for his clandestine articles appearing in the press of the left wing of the Socialist party, notably *Die Freiheit*. The genesis of the Spartacans, however, ought to be traced to the very beginnings of the Great War, to August 1914, when the extreme wing of the great Socialist party in Germany first showed signs of a desire to secede from the party as a whole, as being unalterably opposed to the whole war which they deemed as being engineered by capitalis-

tic and militaristic influences and, therefore, to be condemned *in toto*. This desire not long after they carried out openly, constituting themselves as a new party in the Reichstag, in opposition to all others, and refusing throughout the remainder of the war to vote for supplies and funds to sustain it. When the split took place, out of a total of 108 party members in the Reichstag, 19, subsequently increased to 23, left the Socialist party and called itself the Independent. After the rather tame revolution that ousted the kaiser in the beginning of November, 1918, and led to the overturn of the whole imperial régime and the armistice itself, this Independent, or as later denominated, Spartacan, party veered further to radical tenets, becoming, in fact, communistic, even occasionally anarchistic, in its aims and practices, and not only leaning to, but affiliating with, the Bolshevik party of Russia. Karl Liebknecht himself aided in this molting process, but was murdered in the streets of Berlin, together with his ablest lieutenant, Rosa Luxemburg (q.v.), before the full development of that party movement. The adoption of the title of Spartacans has been considered by many a rather curious thing, since the rising of the Roman slaves under Spartacus came to a speedy evil end and left no trace behind it.

WOLF VON SCHIERBRAND.

SPARTACUS, spär-ta-kūs, Roman insurrectionist: b. Thrace: d. Lucania, 71 B.C. He was captured by the Romans, sold as a slave, and trained as a gladiator at Capua. Here he headed a fight for freedom and succeeded, with 70 comrades, in reaching the crater of Vesuvius, where he was soon joined by other fugitives. His force quickly grew to large proportions and he gained several battles. Spartacus now proclaimed the abolition of slavery, and, being joined by the slaves of the South, passed Rome with a victorious army of about 100,000 men and advanced into the region of the Po. His plan was to lead his army out of Italy and disband it, so that the freed slaves might return to their homes. Despite dissensions and disaffections which arose, he successively met and defeated the two consuls sent against him (72 B.C.). But the slaves, flushed with success, refused to follow their leader out of Italy and demanded to be led against Rome. Spartacus therefore conducted them into winter quarters at Thurii, where Licinius Crassus was sent against him. Having defeated two legions of that general's command, he broke through the obstacles which Crassus had interposed and marched toward Rome. He was overtaken, however, and owing to the dissensions in his army was defeated. Attempting to cross into Sicily, he was betrayed by Sicilian pirates and a portion of his army was captured by Crassus. With the remainder Spartacus won new victories, but in a decisive battle with Crassus on the river Silarus his army was annihilated, Spartacus himself being slain.

SPARTANBURG, S. C., city and county-seat of Spartanburg County, situated at the foot of the Blue Ridge Mountains, on the main line of the Southern Railway, and on the Charleston and Western Carolina, the Carolina, Clinchfield and Ohio, and the Piedmont and Northern railroads, about 100 miles northwest of Columbia. The city is within a few hours

of the great eastern markets and the coal fields of Tennessee, Virginia, West Virginia and Kentucky. It is an agricultural region in which cotton is the principal product. It has an agreeable climate, without extremes. The average annual rainfall is 54 inches and the average temperature 51° F. The educational institutions include Wofford College for Young Men; Converse College for Young Women; Cecil's Business College; several private schools and a first-class public school system. The city is the home of the South Atlantic States Music Festival. It has 100 miles of paved sidewalks and 16 miles of paved streets. The eight city banks have combined resources amounting to \$11,400,000; postal receipts in 1917-18 amounted to \$338,000, due to the proximity of Camp Wadsworth, where 125,000 soldiers were trained. The tax valuation of the city is \$10,000,000, an increase of 34 per cent since 1915. The city has a fine Y. M. C. A. building, Y. W. C. A., several churches, five hospitals and several clubs.

Spartanburg County ranks first in South Carolina in invested capital and value of annual products of industrial concerns, nearly all of which are located in Spartanburg. The average cotton crop is 68,000 bales, while 147,000 bales are manufactured. There are 27 mill corporations operating 36 mills, with 834,000 spindles and 20,600 looms. The value of the manufactured product is \$35,000,000. The capital invested amounts to \$14,600,000. The city has excellent hotels, two of which are modern fire-proofed structures. The city has adopted the commission form of government. The site of Camp Wadsworth, embracing 1,350 acres with perfect water and sewerage systems, has been purchased from the government and is being offered for suburban homes and industrial development. There is a municipally owned water-system in Spartanburg, with a capacity of 10,000,000 gallons. Pop. within corporate limits, 25,000; including suburbs, 35,000.

SPARTEINE (derived from the Latin *spartum* and the Greek *σπάρον*, Spanish broom), an alkaloid discovered by Dr. Stenhouse in 1851, and obtained from the tops of the broom-plant. It is a thick, colorless, transparent oil, with a peculiar, unpleasant odor and a very bitter taste. It boils at 288°, is strongly alkaline, slightly soluble in water, very poisonous, and resembles nicotine in its compounds. Its sulphate is used in medicine as a cardiac stimulant.

SPARTEL, spēr-tél', Cape, Morocco, Africa, the northwestern extremity of the continent. It is a promontory 1,030 feet high, situated at the western entrance to the Strait of Gibraltar.

SPARTINA. See GRASSES IN THE UNITED STATES.

SPASM, an involuntary, convulsive contraction of a muscle or set of muscles which is of a more or less tonic or prolonged character. When similar involuntary contractions are intermittent or clonic in character they are called convulsions. Convulsions usually imply some disturbance of the motor cortex of the brain. Spasms are generally of purely local origin; they are cramps. Spasms are sometimes held to be synonymous with tics (q.v.). In this sense it is the more modern distinction to

regard spasm as a local irritant reflex act, convulsion an involuntary cortical reaction, and tic a muscular movement, originally voluntary, but become involuntary by frequent repetition. The word spasm, however, is used in all three conditions. Spasms occur in many forms of nervous disease, particularly in chorea, hysteria, hiccough, hydrophobia (q.v.), etc. The so-called facial spasm is a form of tic; bronchial asthma is a purely spasmodic affection of the muscular tissues of the bronchi; whooping-cough is largely spasmodic in its character.

SPASMODIC SCHOOL, in literature, a name applied in England to a group of English poets about the middle of the 19th century, among whom were Philip James Bailey, Sydney Dobell and Alexander Smith. The name implied the use of an overstrained and unnatural sentiment and expression, which sometimes grew out of sheer affectation.

SPAULDING, Rolland Harty, American public official: b. Townsend Harbor, Mass., 15 March 1873. He was educated at Phillips Academy, Andover; engaged in the manufacturing business in 1895, and is now member of Jonas Spaulding Sons, manufacturers of leatherboard, counters, novelties, etc., at Townsend Harbor, Mass., Rochester, North Rochester and Milton, N. H., and Tonawanda. Mr. Spaulding is also interested in several other manufacturing enterprises. He served as delegate to the Republican National Convention in 1912 and was governor of New Hampshire in 1915-16. In 1918 he was a candidate for United States senator.

SPAVIN, a disease of horses affecting the hock-joint. It occurs under two principal forms. In young, weakly or overworked horses the hock-joint is sometimes distended with dark-colored thickened synovia or joint-oil. This is bog spavin. Fomentations, occasional friction, a laxative diet, and rest should be diligently tried; and if such remedies prove unsuccessful the swelling must be dressed with strong blistering ointment or fired. The second variety, bone-spavin, is the more common. Toward the inside of the hock, at the head of the shank-bones, or between some of the small bones of the hock, appears a bony enlargement. At first there is tenderness, with heat, swelling, and considerable lameness; but as the inflammation in the bone and its investing membrane abates, the lameness may entirely disappear, or but a slight stiffness may remain. In recent and slight cases cold water should be applied continuously; but in serious cases, when the part is swollen and tender, hot fomentations are best. For several days they must be perseveringly employed. When the part is again cool and free from pain an iodide of mercury or fly-blister should be applied, and the animal treated to three months' rest in a small paddock, the end of a barn, or a roomy box-stall. In persistent cases firing or setoning usually gives much relief.

SPAWN, the eggs or ova of fishes, frogs and other of the larger aquatic animals. See Egg, and the names of various animals.

SPAWN-EATER, a local name for one of the commonest of brook-minnows or shiners (q.v.) (*Notropis hudsonius*), which is likely to eat the eggs of other fishes.

SPEAKER, one who presides over a deliberative assembly, preserving order, and regulating the debates; as, the speaker of the House of Representatives, the speaker of the House of Commons, etc. The Speaker of the House of Representatives is chosen by ballot from among the members upon the assembling of Congress, and occupies that office till the expiration of the body by adjournment *sine die*. If an extra session be called there is no new election of speaker, the same officer presiding over the deliberations. The presiding officer in the Senate is styled the president of the Senate, and he is not elected by that body, the office being held *ex officio* by the Vice-President of the United States. The speaker of the House of Representatives exercises large influence on legislation, and representing, as he does, the majority in Congress, he is usually sustained.

The speaker of the British House of Commons receives a salary of £5,000 a year, with a furnished residence. He is a member of the Privy Council, and ranks after the barons. On vacating his post he receives a pension of £4,000 and is raised to the peerage. The first time a speaker was appointed by this title was in the reign of Edward III, when Sir T. Hungerford was elected. On the Continent of Europe the presiding officer of a legislative body is commonly designated by a title meaning "president." See UNITED STATES—SPEAKER OF THE HOUSE OF REPRESENTATIVES.

SPEAKING TRUMPET, a metallic instrument of a somewhat conical form used for conveying the sound of the voice to a distance. The advantage of the conical form is satisfactorily explained on the assumption that waves of sound are reflected in the same way as rays of light, the angle of incidence and the angle of reflection being the same; for on this assumption it is evident that waves of sound proceeding from the narrow to the wide end of a truncated cone, from the walls of which they are reflected according to the law referred to, will gradually make smaller angles with the axis of the cone; or in other words, the direction of the sound will gradually become more nearly parallel to that axis. A cylindrical tube of uniform diameter has not the same effect, and accordingly is of no use in determining the direction of sound after it leaves the tube, although, as is seen in the case of speaking tubes used in offices, industrial establishments and private houses, it is of great service in transmitting sound from one extremity to the other. Speaking-trumpets are chiefly used at sea, especially in windy weather, to convey commands from one part of the ship to another, and sometimes to speak with another ship.

SPEAR, Charles, American philanthropist and author: b. Boston, Mass., 1 May 1801; d. Washington, D. C., 18 April 1863. After several years' service as a Universalist minister in Brewster and Rockport, Mass., he settled in Boston, where he became well known by his advocacy of prison reform, and his efforts to secure the adoption of legislative measures for the benefit and reformation of prisoners. He visited penal institutions; made suggestions for the more humane treatment of convicts, housed many of them when discharged, and was active in securing employment for them and in pro-

moting their spiritual welfare. He died of an infectious disease contracted in Washington during the Civil War while seeking to ameliorate the condition of prisoners of war. He was a regular contributor to several religious periodicals, was editor of 'The Prisoner's Friend' (1848-54); and was the author of 'Names and Titles of Christ' (1842); 'Plea for Discharged Convicts' (1844); 'Voices from Prison' (1849), etc. Consult Catharine Swan Brown, 'Life of Charles Spear' (1888).

SPEAR, Ellis, American soldier and government official: b. Warren, Knox County, Me., 15 Oct. 1834. He was educated at Bowdoin College, graduating in 1858. During the Civil War he served in the national army, rising from the grade of a captain of Maine volunteers to colonel and commanding a regiment in the Army of the Potomac from 1863 to 1865. He was conspicuous as major commander of a brigade at Peebles Farm and was made colonel for his bravery in action. In 1865 he was brevetted brigadier-general, became inspector of division, and before the close of the war was given the command of a brigade. At the end of the war he became identified with the United States Patent Office, and became commissioner of patents (1877-78).

SPEAR, James, American manufacturer: b. Mauch Chunk, Pa., 17 Feb. 1827; d. Wallingford, Pa., 30 Jan. 1902. He engaged in the manufacture of stoves in Philadelphia, 1848, invented various improvements in heating appliances, among them the anti-clinker grate now generally used, and he also invented the first practical car-heater. He was one of the founders of the Hayes Mechanics Home, a benefactor of various institutions, particularly the University of Pennsylvania, and was actively interested in the Blind Men's Home.

SPEAR, Samuel Thayer, American Presbyterian clergyman and author: b. Ballston Spa, N. Y., 4 March 1812; d. Brooklyn, N. Y., 1 April 1891. He studied medicine, graduating in 1833 at the New York College of Physicians and Surgeons, but entered the ministry in 1835, after training at Troy, N. Y. After a pastorate at Lansingburg, N. Y., he was in charge of the South Presbyterian Church of Brooklyn, N. Y., from 1843 to 1871, when he became connected with the editorial staff of 'The Independent.' He was author of several works, including 'Religion and State' (1876); and 'The Bible Heaven' (1886).

SPEAR, a weapon of offense, consisting of a wooden shaft or pole varying in length up to eight or nine feet, and provided with a sharp piercing point. The spear may be regarded as the prototype of the various forms of piercing weapons, such as the arrow, bolt and dart, which are projected from bows, catapults or other engines, and the javelin, assegai and lance, held in or thrown by the hand. The longer and heavier spears and lances are mainly retained in the hand while in use, but there is no absolute distinction, and the throwing of a spear has in all ages been a form of offensive warfare.

In its earliest form the spear would naturally consist of a simple pole of tough wood sharpened to a point at one extremity, which point might be both formed and hardened by charring

in fire. From this an improvement would consist in fitting to the shaft a separate spear head of bone, as is still practised among primitive races.

The war lance of the mediæval knights was 16 feet long; the weapon of modern cavalry regiments known as lancers may be from 8½ to 11 feet long, usually adorned with a small flag near the head. The Persians at the present day forge spear heads for ornamental purposes only, with two and sometimes three prongs. The modern spears of savage tribes, used equally for hunting and for warlike purposes, are frequently barbed with fish and other bones, and their fighting spears have sometimes poisoned tips. Among civilized communities the hunting spear continues to be used for following the wild boar and other large game, while the Cossacks of Russia and various corps in the armies of western Europe are armed with spears or lances, which experience has shown to be efficient weapons for cavalry. The spear was not an ordinary weapon among the North American Indians, who, before the introduction of the musket among them, used the bow and arrows and the tomahawk.

SPEARFISH, S. Dak., city in Lawrence County, 10 miles northeast of Deadwood, on the Chicago, Burlington and Quincy Railroad. It has a high school and is the seat of a State normal school. The surrounding region is devoted to fruit and stock-raising. There are manufactures of flour and lumber products, a stucco mill and cyanide plant. Pop. 1,130.

SPEARFISH. (1) One of the carp-suckers (q.v.), a species (*carpiodes velifer*) of the Mississippi Valley; (2) a large deep-sea, predatory fish of the warmer parts of the Atlantic allied to the sailfishes (q.v.), and placed in the genus *Tetrapturus*; the best-known species is the billfish (*A. imperator*), called aguja by Spanish-speaking fishermen.

SPEARMAN, Frank Hamilton, author, b. Buffalo, N. Y., 6 Sept. 1859. He was educated at public and private schools in Appleton, Wis., and at Lawrence College. He engaged for some years in commercial life; then from 1895 devoted himself to literary work. He is the author of 'The Nerve of Foley' (1900); 'Held for Orders' (1901); 'Doctor Bryson' (1902); 'The Daughter of A Magistrate' (1903); 'The Close of the Day' (1904); 'The Strategy of Great Railroads' (1904); 'Whispering Smith' (1906); 'Robert Kimberly' (1911); 'The Mountain Divide' (1912); 'Merrillie Dawes' (1913); 'Nan of Music Mountain' (1916), and contributes short stories to magazines and economic articles to reviews.

SPEARMINT, a European labiate herb (*Mentha spicata*), which has become perfectly naturalized in America, and is often found in damp places. It is about two feet high, smooth, square-stemmed, and spreading by leafy stolons. It bears opposite, lanceolate, sharply serrate, smoothish leaves, and small, two-lipped, purplish flowers in slender verticillate spikes, which are both lateral and terminal, the latter being the longest. Spear-mint is cultivated for its very aromatic foliage, which yields a carminative oil, and was an old-time remedy for flatulence. It is now chiefly employed, with vinegar, as a fitting sauce for roast lamb, and sprigs of it

are the crowning feature of the seductive mint-julep.

SPEARS, spērz, John Randolph, American author and journalist: b. Van Wert, Ohio, 21 April 1850. Among his many publications are 'The Gold Diggings of Cape Horn' (1895); 'The Port of Missing Ships' (1896); 'The History of Our Navy' (1897); 'The History of the American Slave Trade' (1900); 'Anthony Wayne' (1903); 'The History of the Mississippi Valley' (1903).

SPECIAL SESSIONS, Court of. See COURT.

SPECIE (sp'eshē) **CIRCULAR**, a treasury circular drafted by Senator Benton and issued at President Jackson's orders 11 July 1836, which directed that nothing but gold and silver should be received in payment for the public lands. The next Congress passed a bill to rescind this specie circular, but President Jackson killed it by a veto. It was claimed by President Jackson's opponents that the circular contributed greatly to bring about the ruinous financial crisis of 1837.

SPECIE PAYMENTS, in finance, a payment in coin or any metallic money; a medium of exchange authorized by the government or State. In modern times specie is largely used by banks as security for paper money in circulation. In times of financial stringency the amount of coin on hand is inadequate to cover the volume of paper in circulation; hence arises a temporary condition called suspension of specie payment. When conditions change and finances improve a resumption of specie payments generally ensues.

SPECIE RESUMPTION. The resumption of specie payments after the close of the American Civil War was a subject of long and anxious discussion in Congress and in the press. In 1861 payment in specie was suspended by the government and by banks throughout the United States, and Congress authorized the issue of United States notes to meet the expenses of the conflict, and to be accepted as legal tender for all dues except customs. The receipt of specie for customs duties kept the treasury well supplied with gold and silver, and enabled the government to meet obligations payable in coin. After the war, and indeed from the closing scenes of the Confederacy, the premium on gold gradually fell until it was merely nominal, but the fact that the government's paper currency was not redeemable on presentation in coin kept that currency from being at par, and tended to unsettle business, and to provoke, or afford an excuse for serious financial crises. The question of resumption was most earnestly agitated after the panic of 1873, and on 14 Jan. 1875 an act was passed by Congress, ordering the resumption of specie payments to begin on 1 Jan. 1879. The approach of that date was attended by great apprehension in the United States and abroad that the national treasury would be unable to meet the overwhelming demand for specie that many expected to occur. The mints were run far beyond the usual hours coining money to meet possible requirements, and there was much surprise when the appointed date came, and very little currency was presented for redemption. The people were satisfied of the gov-

ernment's ability to pay, and gold at once fell to par. "Greenbacks," as the national currency is called, became the equivalent of gold throughout the world, and have ever since maintained that position.

SPECIES, a group of individuals which agree in exhibiting certain distinctive hereditary characters of sufficient importance to render a particular name convenient. When we familiarly talk of the different "kinds" of plants and animals, we indicate in a rough way the biological ideal of species; and the recognition of raven, jackdaw and rook, as different kinds of crow, corresponds with the scientific distinction of these as four different species of the genus *Corvus*. (See GENUS). In many a case, however, where the distinctive hereditary characters are less conspicuous, the ordinary observer may see only one "kind" where the trained naturalist detects many "species." Moreover, where a naturalist unfamiliar with the details of a particular class of animals might discern only half a dozen distinct species, the specialist might distinguish a score. In fact, the conception of species is entirely relative to convenience; where the "lumpers" think a score of special groups with special names quite sufficient, the "splitters" may think it necessary to distinguish a hundred. Except in cases where the limitations of group from group are very clear, as in the case of the four "kinds" of crow above mentioned, it requires a period of criticism before a satisfactory compromise between the "lumpers" and the "splitters" can be arrived at. And the reason for this is simply that in many cases one species is linked to another by intermediate varieties, and it may be, also by hybrids.

Collections of definitions of "species" have often been made; and the curious will find a score in Quatrefages' posthumous work, 'Darwin et ses précurseurs Français.' Thus, Linnaeus wrote: "Species tot numeramus quot diversæ formæ in principio sunt creatæ." Buffon defined species as "a constant succession of individuals similar to, and capable of reproducing each other." De Candolle said that a species was "an assemblage of all those individuals which resemble each other more than they do others, and which are able to reproduce their like, in such a manner that they may be supposed by analogy to have descended from a single being or a single pair." Quatrefages' idea of species is summed up in his statement that it is "an assemblage of individuals more or less resembling one another, which are descended, or may be regarded as being descended, from a single pair by an uninterrupted succession of families." Müller says species is a "living form, represented by individual beings, which reappears in the product of generation with certain invariable characters, and is constantly reproduced by the generative act of similar individuals." These illustrations may suffice to impress the fact that the *invariable* nature of species had become firmly fixed on the minds of the older naturalists in former years.

A species, it may safely be concluded, represents no immutable, fixed or unvarying group, but a very variable one, differing widely in the extent of its variation in different cases. A species is a relative and subjective conception; the reality is in the component individuals. See

SPECIES, Extinction of. See EXTINCTION OF SPECIES.

SPECIFIC DUTIES. See DUTY.

SPECIFIC GRAVITY. The specific gravity of a body is the ratio of the mass of that body to the mass of an equal volume of some standard substance which is arbitrarily selected for purposes of reference. In the cases of solids and liquids it is customary to select water as the standard substance; and water is always understood, in connection with solids and liquids, unless the contrary is explicitly stated. Gases are also sometimes referred to water, but it is much commoner to compare the density of a gas with that of air or hydrogen. The specific gravity of a solid which is not affected by contact with water may be determined by weighing the solid twice—once while it is surrounded with air, and once while it is submerged in water. The difference between the two weights so obtained gives the weight of a mass of water whose volume is equal to that of the solid; and hence, in order to determine the specific gravity of the solid, it is only necessary to divide the weight as observed in air by the loss of weight when it is submerged in water. If the solid is soluble in water, or if it is affected by water in any other manner, its specific gravity must be determined by some indirect method. Many such methods are known. For example, we may replace the water by some other liquid, such as benzene, in which the solid is not soluble, and then perform the experiment precisely as described above. The result so obtained is the specific gravity of the substance with reference to the benzene (or whatever liquid is employed in its place); and in order to express the specific gravity of the body with reference to water we have merely to multiply its specific gravity with respect to benzene by the specific gravity of the benzene as compared with water.

The specific gravity of a liquid may be determined very accurately by means of the "specific gravity bottle." This is a bottle made of thin glass (so as to be light), and provided with a ground-glass stopper. The weight of the bottle is determined (1) when it is empty, (2) when it is filled with water, and (3) when it is filled with the liquid whose specific gravity is desired. From these data we can easily determine the weight of the water in the bottle, and also that of the second liquid; and upon dividing the latter by the former we obtain the specific gravity sought. The specific gravity of a liquid may be obtained more expeditiously (though less accurately) by means of the simple instrument known as the hydrometer. This consists essentially of a glass bulb (usually cylindrical in shape), provided at its upper end with a graduated stem and weighted at its lower end with shot or mercury, so that it will float in an upright position when placed in a liquid sufficiently dense to permit it to float at all. It is evident that such an instrument will be buoyed up more by a dense liquid than by a lighter one; and when the stem at its upper end has once been graduated correctly we have only to place the hydrometer

in the liquid whose specific gravity is desired, and observe the depth to which it sinks, as read from the graduated stem. In Fahrenheit's form of the instrument there is only one graduation mark on the stem; but a small pan is provided at the top of the hydrometer, and the observation consists in determining what weights must be placed upon this pan in order to cause the instrument to sink to the standard level indicated by the mark on the stem. Hydrometers are often graduated for special purposes, so that instead of indicating the specific gravity of the liquid in which they are placed, their readings give at once the percentage of alcohol (or of some other substance) that is present. Such instruments are called alcoholometers, salinometers, lactometers, etc., according to the special kind of liquid for whose investigation they are graduated.

As the density of water varies with the temperature, it is necessary (if we are to have a standard of density that is definite and accurate enough for scientific purposes) to specify the temperature of the water with which the comparison is made. In England the standard temperature of the water was formerly taken at 62° F.; but it is now the almost universal practice to make the comparison with water at its temperature of maximum density, or at about 39° F. In the vicinity of this temperature, the density of water varies very slowly with the temperature, and hence in comparing the density of a substance with that of water at or near 39° F., it is not essential to observe the temperature of the water with any high degree of precision. It was, indeed, this convenient and practical fact which led to the adoption of 39° F., as the standard temperature of the water.

Following are the specific gravities of various substances, as compared with water at 39° F.; the temperature of the substances being

TABLE OF SPECIFIC GRAVITIES.

Aluminum.....	2.68
Antimony, cast.....	6.71
Bismuth, cast.....	9.82

Ether (at 70° F.).....	0.72
Alcohol, absolute.....	0.79
Bromine (at 32° F.).....	3.19

also supposed to be 39° F., except when otherwise specified. It is to be understood that the specific gravity of a solid varies to some extent with the physical condition of the solid. The foregoing values, however, are sufficiently accurate for general purposes; and more precise information is given in this encyclopedia, in many cases, in the articles upon the several substances named.

The term specific gravity is not now used as commonly as it formerly was, the density of the substance being spoken of instead; it being understood in such cases that it is the density of the substance relatively to water that is meant, and not its absolute density as expressed in units of mass per unit of volume. In the system of units employed in the United States and in England, this double use of the word density may sometimes lead to confusion. The metric system is now, however, very largely used in scientific work, and here the confusion cannot well occur; for in the metric system the unit of mass (the gramme) is the mass of a cubic centimeter of water at its temperature of maximum density; and hence, in this system, the "absolute density" of a substance, and its "density relatively to water," are one and the same thing.

In the case of gases the expression specific gravity is now almost never used; density having practically displaced it. The accurate determination of the density of a gas is very difficult, and calls for great experimental skill and the finest of apparatus. In the usual method of performing such a determination a pair of glass globes, as nearly identical as possible, are suspended from the respective arms of a delicate balance and weights are added at one end or the other until perfect equilibrium is attained. One of the globes is then thoroughly exhausted by means of an air-pump, while the other is filled with the gas under examination. The equilibrium of the balance will be destroyed by this process, and if we restore it by adding weights to the arm carrying the exhausted sphere we shall thereby ascertain the weight of the gas in the other sphere. By repeating the experiment with gases of different kinds the weights of equal volumes of these different gases will be ascertained; and if the various weights so obtained are all divided by the weight as obtained for hydrogen (for example), the quotients will be the densities of the various gases, with respect to hydrogen. The relative densities of some of the more familiar gases are given in the following table, it being understood that the pressure in every case is one atmosphere, and the temperature 32° F. The relative densities of the gases here given do not change much for considerable variations of temperature and pressure; but this constancy is only approximate, not absolute; and hence, in the interest of accuracy, it is desirable to state (as follows) the precise conditions under which the table is exact.

According to the experiments of Regnault, a cubic centimeter of hydrogen, at the freezing point of water and under a pressure of 760 millimeters of mercury at Paris, weighs 0.00008956 grams; and from this fundamental constant it is easy to find the weight, under

DENSITIES OF GASES, RELATIVELY, TO HYDROGEN.

Hydrogen.....	1.000
Methane ("marsh gas").....	8.118

ALLAN D. RISTEEN, PH.D.

SPECIFIC HEAT. Maxwell defines this expression as follows: "The specific heat of a body is the ratio of the quantity of heat required to raise (the temperature of) that body one degree, to the quantity required to raise (the temperature of) an equal weight of water one degree." For most engineering purposes, and for rough calculations of all kinds, this definition is sufficiently accurate. It assumes, however, that the quantity of heat required to raise the temperature of one pound of water by one degree is the same in all parts of the thermometric scale; and while this is approximately true, it cannot be admitted when we have to deal with heat-measurements of a high order of precision. We must then define the specific heat of a body as the number of units of heat that must be added to a unit mass of the body, in order to raise the temperature of the body by one degree; a unit of heat being simultaneously defined as the quantity of heat that is required in order to raise the temperature of a unit mass of water by one degree at some particular part of the thermometric scale. Various suggestions have been made as to the particular temperature that the water should have, in the definition of the unit of heat; and different experimenters have used different units, to the great confusion of the subject of heat-measurement in general. There is now a marked tendency toward the general adoption of a temperature of about 15° C. (59° F.); so that a unit of heat would be defined (in the metric system) as the quantity of heat that is required to raise the temperature of one gram of water from 14.5° C. to 15.5° C.; and in the familiar English and American system the unit would be similarly defined as the quantity of heat required to raise the temperature of a pound of water from 58.5° F. to 59.5° F. Adopting this definition of the unit of heat, we may speak of the specific heat of water itself; the specific heat of that fluid at t° C. being the quantity of heat required to raise the temperature of a certain mass of water by one degree at t° C., divided by the quantity of heat required to raise the temperature of an equal mass of it by one degree at the temperature 15° C. It is easily seen that it is of the highest importance to the physicist to know precisely how the specific heat of water (as thus defined) varies with the temperature t° ; and it might not unreasonably be assumed that this fundamental matter would early have received a satisfactory amount of attention. Such

was not the fact, however. Regnault indeed made an elaborate study of the subject, and published his results in the tenth memoir of his first series (1847). His conclusions were accepted for many years, but it is now known that they are incorrect, the data that he gives being even inconsistent among themselves. The general acceptance of Regnault's work on the specific heat of water has vitiated many otherwise important researches on the subject of heat; but we are now in possession of data that appear to be very much superior, and the confusion that has prevailed in the past is likely to be avoided in the future. (With reference to Regnault's work on water, see a letter by J. Macfarlane Gray in *Engineering* for 9 Jan. 1885, p. 42; also a more extended discussion in the same journal for 12 July 1889, p. 57; also E. H. Griffiths, *Philosophical Magazine*, November 1895).

Rowland, in connection with his famous work on the mechanical equivalent of heat (1879), carefully investigated the specific heat of water over a range of temperature extending from 0° C. to about 40° C., and he first showed that in this interval the specific heat of water decreases with rising temperature, attaining a minimum value somewhere about the temperature 30° C. (Rowland, 'Physical Papers,' p. 387). Other experimenters have since corroborated his results; but it was not until 1902 that a complete series of apparently satisfactory measurements of the specific heat of water from the freezing-point (q.v.) to the boiling-point (q.v.) were published. These are due to H. T. Barnes, of McGill University, Montreal. Mr. Barnes assumes 16° C. as the temperature at which the specific heat is unity (that is, he takes, as his unit of heat, the quantity of heat required to raise the temperature of a gram of water by 1° C., at 16° C.). His results ('*Philosophical Transactions*,' A, Vol. 199, p. 149) are as follows:

SPECIFIC HEAT OF WATER AT VARIOUS TEMPERATURES, IN TERMS OF A THERMAL UNIT AT 16° C. (BARNES).

Temperature	Specific heat	Temperature	Specific heat
5° C.	1.0053	55° C.	0.9985
10	1.0023	60	0.9991
15	1.0003	65	0.9997
20	0.9990	70	1.0004
25	0.9981	75	1.0010
30	0.9976	80	1.0017
35	0.9974	85	1.0024
40	0.9974	90	1.0030
45	0.9976	95	1.0037
50	0.9980		

The variation, as will be seen by the table, is quite small, and for many purposes the specific heat of water may be taken as unity at all temperatures. This will be assumed to be the case in the illustrations and explanations which follow; for the corrections which must be made in order to take the actual variation into account are tedious, and their accurate comprehension and application imply a certain knowledge of practical physics which the reader cannot be assumed to possess.

The specific heat of a body which is not affected by contact with water may be deter-

mined by heating the body to a known temperature, and then immersing it quickly in a definite mass of water whose initial temperature is also known. If we denote the mass of the water by W and that of the body under investigation by M , and if T_1 is the initial temperature of the water, and T_2 that of the body, and if S is the specific heat of the body and T is the final temperature that the body and the water have in common, we may calculate the specific heat, S , as follows: The temperature of the water has been raised from T_1 to T , and the mass of the water is W pounds, or grams, as the case may be. Then it follows that the number of units of heat that have been absorbed by the water is $W(T - T_1)$. Similarly, the body has cooled from T_2 to T , and its mass is M . Hence if the body had a specific heat precisely equal to that of water, we should know that it had given up $M(T_2 - T)$ units of heat. Its actual specific heat, however, is S ; and hence it follows, by the definition of specific heat, that the actual quantity of heat given out by the body is $SM(T_2 - T)$ units. As we shall suppose that the radiation and conduction of heat between the apparatus and outside objects is negligible, it follows that the quantity of heat given out by the body is equal to the quantity absorbed by the water; that is, we must have the equation

$$W(T - T_1) = SM(T_2 - T)$$

And from this we easily find

$$S = \frac{W(T - T_1)}{M(T_2 - T)}$$

In the actual conduct of an experiment of this kind there are many difficulties to overcome, and many corrections to be estimated and applied. There is always more or less communication of heat between the apparatus and outside objects, and the heat that is given out by the cooling body warms not only the water, but also the containing vessel, the thermometers and the stirring apparatus.

In determining the specific heat of a body advantage is often taken of the known fact that the quantity of heat required to melt one pound of ice at 32° F. is approximately the same as the quantity of heat required to raise the temperature of one pound of water by 140° F. In the application of this fact to the determination of specific heats the body under investigation is surrounded by ice, and the number of units of heat that are given off is determined by observing the quantity of ice that is melted, and multiplying that quantity (as expressed in pounds) by 140. Bunsen devised a very delicate apparatus for the execution of this sort of measurement. In his instrument the body to be studied is placed in a cup-shaped depression in a glass vessel that is filled with ice and water, and which is entirely sealed, save for a graduated capillary tube, one end of which enters the mixture of ice and water, while the other end projects into the air. The quantity of ice that is melted by the heat given off from the body is not directly observed, but is inferred from the change in volume of the ice-and-water mixture, as indicated by the motion of an index drop of mercury in the capillary tube; it being known that ice upon melting contracts by about one-twelfth of its own volume.

The specific heat of a gas is defined in precisely the same way as the specific heat of any

other body; but in the case of gases it is necessary to specify the way in which the change of temperature of the gas takes place. Thus we may heat a gas while we maintain its pressure constant (permitting the volume to increase as much as it will), or we may heat it while its volume is kept constant (the pressure meanwhile increasing). The specific heats obtained under these two different conditions are quite different in numerical value, and they are distinguished respectively, as the "specific heat at constant pressure" and the "specific heat at constant volume." The specific heat of a gas at constant pressure may be determined with considerable accuracy by causing a stream of the gas to flow through a calorimeter, so that it experiences a definite fall in temperature in its transit. The quantity of heat given up by the gas can be made to be very considerable (and hence easily measurable) by continuing the flow for a sufficient time; and to determine the specific heat at constant pressure, we then have merely to divide the total quantity of heat given out by the gas by the total mass of the gas that has been passed through the calorimeter, and again by the fall in temperature that the gas has experienced. The specific heat at constant volume is more difficult to obtain, and it has usually been determined by an indirect method, rather than by direct measurement. It can be determined directly, however, and apparently with considerable precision, by means of the Joly steam calorimeter.

Following are the specific heats of a number of substances; though it must be remembered that many of them are more or less uncertain, not only because they vary (in the case of solids) from one specimen to another, and from one temperature to another in all substances, but also because in their determination the thermometric and calorimetric work has unfortunately not always been beyond reproach.

TABLE OF SPECIFIC HEATS.

Aluminum	0.2122
Antimony	0.0486
Boron	0.252
Bromine (liquid)	0.1071
Carbon (diamond)	0.113
Carbon (charcoal)	0.194
Copper	0.0933
Gold	0.0316
Iron	0.112
Lead	0.0315
Magnesium	0.245
Mercury	0.0335
Nickel	0.109
Phosphorus	0.170
Platinum	0.0323
Silver	0.0559
Sulphur (freshly melted)	0.184
Tin (cast)	0.0559
Zinc	0.0935
Ice (at 0° F.)	0.504
Alcohol	0.65
Chloroform	0.235
Ether	0.54
Carbon disulphide	0.24
Air	0.2375
Oxygen	0.2175
Nitrogen	0.2438
Hydrogen	3.4090
Carbon dioxide	0.2163
Ammonia gas (NH ₃)	0.508
Methane	0.593

In the foregoing table the results given for gases are the specific heats at constant pressure. Consult Ganot, 'Elementary Treatise on Physics,' and Preston, 'Theory of Heat.'

ALLAN D. RISTEEN, Ph.D.

SPECIFIC PERFORMANCE, in equity, a proceeding to compel the performance of a specific agreement, as the sale of land, when damages would not be an adequate remedy. It is within the discretion of the courts to grant or deny this form of relief, and in their decisions they are guided largely by precedent. It is more commonly decreed in cases of contracts to convey or lease land. Usually it is refused in cases of contracts to convey a chattel unless it is unique and cannot be secured elsewhere. It will not usually be decreed when there is an adequate remedy at law, when it is not reasonably possible, when the complainant has done something inequitable, or when the court cannot enforce or superintend the execution of its decision. Usually specific performance will not be granted in cases of personal services, as those of actors, painters, singers, etc., even if the damages recoverable at law are exceedingly inadequate.

SPECIFICATION, a detailed mention of particulars: (1) *In patent law*, the applicant's statement describing the method of construction and use of the device presented for patent. The description must be sufficiently clear to enable any person with requisite skill to make the article in question; and in United States law the process as described in the specification becomes a part of the patent, any necessary detail omitted being cause for invalidation of the patentee's rights. (2) *In architects', builders' or mechanics' contracts*, the description attached to the plans detailing the materials to be used, method of construction to be followed, the time permitted for the completion of the work and all other items of information which cannot be set forth in the drawings.

SPECTACLED BEAR, the bear of the South American Andes. See **BEAR**.

SPECTACLES, magnifying glasses made as a pair to be fitted over the eyes to aid the vision, supposed to have been invented by Roger Bacon in the 13th century, and used to magnify an object or correct some defect in the organs of vision. Spectacles consist generally of two oval or circular lenses mounted in a light metal frame which is made up of the "bows," "bridge," and "sides." The lenses may be bi-concave, bi-convex, concavo-convex, etc., though lenses forming segments of a cylinder are used in some cases of astigmatism. In long-sighted persons the defect of the eye is counteracted by convex lenses, in short-sighted persons by concave lenses. When made without bows to hold on the ears or hair, and with a spring in the bridge, they are specifically termed eye-glasses, or pince-nez.

Divided or pantoscopic spectacles have each lens composed of two semi-circles of different foci neatly united one above the other; one half for looking at distant objects, and the other for examining things near the eye. Another kind, called periscope spectacles, has been contrived in order to allow considerable latitude of motion to the eyes without fatigue. In such case the concave side of a diverging meniscus lens is placed toward the eye. A modern form is made of plain glass with large rims, as of imitation tortoise shell, for protection of the eyes against sand, etc., as encountered in driving an automobile. Colored lenses of flat glass are employed in spectacles to re-

lieve the eyes of a glare of light. Wings or "blindners" are sometimes added to keep out the dust. Where two lenses are supplied for each eye they are termed compound spectacles or compound lens spectacles. Ordinary standard spectacle lenses are numbered according to the inches of focal distance, a No. 12 involving holding a paper at a distance of 12 inches from the eye to get the correct focus and read easily. Astigmatism (q.v.) is so common that spectacles are frequently made to a prescription, each glass being ground to a curve to correct the inaccuracy of the eye. Consult Crookes, 'Preparation of Eye-Preserving Glass for Spectacles' (1914). See **LENS**; **EYE**; **VISION**.

SPECTATOR, *The*. Tuesday, 12 April 1709, deserves to be remembered as an important date in the history of English literature. For on that day Richard Steele issued the first number of *The Tatler*. This modest half sheet, issued thrice a week, was in reality the beginning of English periodical literature. Defoe had founded his *Review* two years before; but that was a little sheaf of political news and opinions with no charm of literary quality. It was the merit of Steele to perceive the opportunity for a new form of journal which should picture, in entertaining fashion and in a temper of kindly satire, the manners and conduct of contemporary society. He put at the head of his first number a couplet from Juvenal:

"Whatever men do, or say, or think, or dream
Our motley paper seizes for its theme."

Addison, it seems, had not been informed of Steele's project, and did not recognize the hand of his friend until the sixth number. He is supposed to have written the eighteenth paper, but did not join Steele as a regular contributor until near the close of the year 1709. In the next two years his aid became indispensable. As Steele himself said, "I fared like a distressed prince who called in a powerful neighbor to his aid, and when I had called him in I could not subsist without him." On 2 Jan. 1711, *The Tatler* was brought suddenly to an end, but after an interval of two months was followed by that more famous paper, *The Spectator*. *The Spectator* is usually spoken of as Addison's; but in fact it was under the joint conduct of Addison and Steele, and the contributions of the two men were about equal in number.

Yet it is not without good reason that we speak of Addison's *Spectator*. Addison's humor, if less buoyant and convivial than Steele's, was more subtle, delicate and widely observant. Steele was the typical man about town, who threw himself heartily into the life of the hour; Addison was rather, as he styled himself, a spectator who sat in his arm-chair at Buttons and watched the varied play of life about him with quiet, superior satisfaction. Mr. Spectator is always courteous, refined, urbane. You feel in his page the charm of manners and the grace of good society; and if in many of his papers there is a flavor of pretty malice, it is directed against the follies and foibles, the petty meannesses that often hide under outward good breeding. His best papers are doubtless those devoted to this kindly social satire.

Yet it is possible that Addison himself esti-

mated more highly the critical and the ethical essays which usually appeared, the one kind on Fridays and the other on Saturdays. Some of the critical papers, especially the famous series on Milton's *Paradise Lost*, have been greatly admired and frequently reprinted. But the reader of to-day will probably not find them of absorbing interest. Their criticism is purely formal and academic; Addison is trying to prove by Aristotle's rules, that Milton was a great poet. Of all such criticism it may be said that, if the reader knows his Milton, it is needless; if he does not, it is useless. The ethical and religious papers though perhaps less often mentioned, are some of them rather more entertaining. Addison was the son of a dean and always something of a preacher himself. "He's a parson in a tie-wig," said Mandeville. And when the parson in a tie-wig preaches to us from *The Spectator's* chair of a Saturday, the sermon may sometimes be a little prosy, but it is always wholesome and genuine. It is a calm and winning religion Mr. Addison has to recommend, and he exemplified it himself. It is quite possibly true, as some one has said, that *The Tatler* and *The Spectator* did more for English society than all the sermons preached in the Queen Anne time; for they brought religion and morality into fashion.

But most of the humor and the wisdom of *The Spectator* might have perished had it not been for the perfection of the style in which they were conveyed. Steele wrote as he talked, in rapid, careless fashion; he would not stay for careful elaboration or tedious correction. Addison, on the contrary, was careful, even finical in all matters of expression; but his effort issued in a style simple, suave, urbane. He succeeded in combining idiomatic ease with perfect finish as no other writer of his time could do, and very few have done since. Everybody remembers the admiring dictum of Johnson: "Whoever would attain in English style, familiar but not coarse, elegant but not ostentatious, must give his days and nights to the study of Addison." The critic to-day may find his thought lacking in depth, and his manner lacking in energy; but few writers have known better how to marry their thought and feeling with perfect phrase.

The immediate success of *The Tatler* and *The Spectator* is significant of an important change in English society. For some 50 years there had been growing up in England a great middle class, shrewd, intelligent and rapidly gaining wealth. They owned a great part of the national debt that England had been rapidly piling up; they were actively interested in politics; they formed the majority of the Whig party that was to rule for nearly a hundred years. It was this class that furnished for the first time in England a large reading public. By the Queen Anne time they were crowded into London, where they were readily accessible to the pamphleteer and journalist. Eighty thousand copies of Defoe's 'True Born Englishman' were sold on the streets of London, and Swift's 'Conduct of the Allies' ran through four editions in one week. It was Steele and Addison who first hit upon the new literary form adapted to the wants of such a class of readers. They were the creators of English popular literature. It was Addison,

especially, who saw that such writing, however familiar or even trivial its themes, is susceptible of that exquisite finish that ensures its permanence. *The Spectator* had scores of imitators in the course of the century, the most famous of them being *The Rambler* and *The Idler* of Samuel Johnson; but none of them equaled their model in variety of theme or charm of treatment. Consult Johnson, Samuel, 'Lives of the Poets'; Courthope, 'English Men of Letters'; Stephen, Leslie, 'Dictionary National Biography'; Thackeray, 'English Humorists'; 'Cambridge History of English Literature' (Vol. IX, ch. 2).

University.

SPECTROMETER, an instrument having a prism in the centre and telescopes for measuring the angular deviation caused by passing of light through the prism. This determines the degree of refraction of the glass or other substance of which the prism is made. A diffraction grating of polished metal or glass closely ruled in parallel lines may be substituted for the prism in some forms of spectroscopy. In the most familiar type, a three-sided prism is mounted on a central table and a short tube or telescope reflects the light from an outer mirror to a collimating lens to make a beam in which the light rays all are parallel and directed on the prism. Another tube or telescope is positioned to observe another face of the prism, and this observing telescope has cross wires for noting lines accurately. There being a graduated circle in the central table, it becomes a matter of measurement to observe the difference, if any, at which the parallel rays enter and leave the prism. The angle of the faces of the prism has to be considered in making the calculation. With a diffraction-grating the data can be obtained to calculate the wavelength of the light-ray that passes.

SPECTROSCOPE, the instrument employed in spectrum analysis. See **SPECTROSCOPY**.

SPECTROSCOPY. If one observes a Bunsen flame through an ordinary glass prism held close to the eye he will see a succession of colored images of the flame. This series of colored images is called the spectrum of the flame. An instrument, such as the prism, which will separate the various radiations emitted by any source of light, is called a spectroscopy. Spectroscopy is, therefore, defined as that science which has for its object the determination and description of the various radiations which different bodies emit, reflect and absorb. The subject is here treated under seven headings as follows: (1) Preliminary, concerning the Nature of Light; (2) Sources of Radiation; (3) Separation of Radiations; (4) Methods of Recording Radiations; (5) Comparison and Interpretation of Radiations; (6) Summary of Principles; (7) Bibliography.

1. **Nature of Light**.—Present views concerning that form of energy which we call light are based almost wholly upon experimental evidence furnished by Huygens, Newton, Young and Fresnel. Since light is the subject matter of spectroscopy, it is essential, at the outset, that we should understand the modern theory of light as perfected by these four men. Huygens,

2 Spectra of Metals

by assuming that light consists of a wave-motion in the ether, showed that on simple dynamical principles, reflection, refraction and the finite velocity of light might be easily explained. He first interpreted for us the physical constant known as the "refractive index," suggesting that for any medium it is merely the ratio of the speed of light in air to the speed of light in that medium. To Newton we owe two capital discoveries concerning the nature of light. In 1669 he demonstrated experimentally that white light contains all the colors of the rainbow, that the simple prismatic colors obtained by analyzing white light cannot be farther separated into other colors by passing them through prisms, and that color, in general, is merely white light from which has been removed some of its colored constituents. Besides this, Newton established the fact that these luminous disturbances (which he thought of as moods of easy and of difficult transmission, but which we now call light-waves), are not irregular pulses, as Huygens imagined, but are periodic in character. This inference is drawn from the phenomenon known as "Newton's Rings." We come next to the work of Thomas Young (1773-1829) who first demonstrated the fact that, under proper conditions, two rays of light, that is two trains of light-waves, may interfere in such a manner as to produce darkness. Young's explanation of diffraction, however, proved to be utterly insufficient, and for the phenomenon of polarization he could offer no explanation whatever, for the reason that he conceived light-waves to be longitudinal and not transverse vibrations. To summarize Young's work most briefly would be to say that he introduced into optics the principle of interference—or of "non-interference," as suggested by Michelson, since the principle consists merely in the fact that of two light rays

FIG. 1.—An "end on" tube. Shows one form of tube recently employed by Michelson, in which the discharge is viewed from the end, rather than the side of the tube, and which is known, therefore, as an "end on" tube.

meeting at a point each produces its own effect independently of the other. Fresnel (1788-1827), in a certain sense, perfected the wave-theory of light by combining the principle of Huygens with the principle of interference and by introducing the idea that light-waves, unlike sound-waves, are transverse disturbances. Evidence for this view lay in the fact that light can be polarized. We may now summarize the labors of these four men by saying that experiment seems to indicate that light consists in a transverse wave-motion in a medium which pervades all known space and which we call the ether. In space devoid of ordinary matter light

of any color travels with a speed of approximately 186,330 miles per second, while in all ordinary matter light travels with less speed, the amount of diminution becoming greater and greater as we pass from the red to the violet.

Bearing in mind this conception of a train of light-waves, we proceed to consider the general method of spectroscopy. The examination of a body by means of the spectroscope includes, in general, four steps. These are:

- A. The Production of the Radiations.
- B. The Separation of the Radiations.
- C. The Recording of the Radiations.
- D. The Comparison and Interpretation of the Radiations.

We shall in the following four sections consider these four steps.

2. Sources of Radiation.—In practice the spectroscopist is limited to two artificial sources, namely, flames and electric currents. Besides these are many natural sources such as lightning, the aurora borealis, meteors, stars, glow-worms, etc.; but the nature and occurrence of these natural phenomena are so far beyond our control that they do not here call for discussion. Adopting the following classification, we

SOURCES.	Natural...	Lightning, Stars, including the sun, Comets, Aurora, Meteors, Glowworms.
	Artificial...	Flames.... Candle, Alcohol, Bunsen, Oxy-hydrogen, Arc, Electric currents. Brush discharge, Spark.

now proceed to a description of some particular artificial sources.

Candle and Alcohol Flames.—These have mainly a historical interest, as being the first sources in which line spectra were observed. The temperature of the alcohol flame is only roughly known, but is probably not far from 1,300° C. Substances are easily introduced into the flame and the flame itself is fairly colorless. These two qualities combined to make it very useful in the early history of the science.

Bunsen Flame.—The flame which Bunsen devised in 1856 has three marked advantages as a spectroscopic source, namely, it is simple in construction and operation; its outer mantle is almost totally devoid of any characteristic spectrum of its own; and it possesses a high temperature. Many measurements of the temperature of this flame have been made, but there is good reason for believing that nearly all of these are under-estimates. The most reliable measurement is probably that of Wegener, at Berlin, who obtained 1,788° C. for the outer mantle. The temperature of the violet mantle is probably about 100° or 200° less; while the temperature of the inner dark cone ranges from 250° to 500° C. The substance whose spectrum is desired may be introduced into the flame in a great variety of ways. Bunsen used a bead of the material on a platinum wire; sometimes a piece of asbestos is convenient; Gouy uses the spray from an atomizer; Eder and Valenta have employed a platinum wire-gauze wheel to transport the solution from a dish to the flame.

Oxyhydrogen Flame.—This flame is also nearly colorless, has an exceedingly high tem-

perature and gives spectra approximating those obtained in the electric arc. It has been used with great skill by W. N. Hartley.

Electric Arc.—This source has been in common use since the invention of the Gramme dynamo, 1876. The arc is generally used in one of two ways, either by drilling holes in the carbon rods and filling these holes with the material whose spectrum is desired, or by making the electrodes directly and entirely out of the substance which is being studied. This latter method is, of course, practicable only in the case of materials which conduct electricity. The temperature of the carbon arc is not accurately known, but probably lies between $3,500^{\circ}$ and $3,900^{\circ}$ C. As a spectroscopic source it is admirable in nearly every respect except that in those regions of the spectrum which are most easily studied carbon has a strong spectrum of its own which is always superposed upon that of the substance under investigation. In the case of metals, the easiest method of avoiding this difficulty is to use a rapidly rotating metal disc for one electrode and a metal rod for the other. The incandescent metal vapor thus obtained yields the purest spectra known.

Electric Spark.—Of all sources of radiation that which is most generally convenient and most widely used is perhaps the electric spark, obtained by use of an ordinary induction coil. Spark discharges may also be obtained from an electrostatic machine, such as the Wimshurst, from a Tesla coil, or even from a high voltage storage battery. In general the electric spark produces two spectra, namely, the spectrum of the electrodes and the spectrum of the air or other gas between the two electrodes. But, as was discovered by Plücker in 1858, the spectrum of the electrodes may be avoided by enclosing them in a partial vacuum. Under these conditions one gets only the spectrum of the surrounding gas; so that now the almost universal method of studying the spectra of gases is to seal platinum electrodes into a glass tube and then fill the tube under low pressure with the gas to be studied.

The converse problem of getting the spectrum of the electrodes, without that of the surrounding gas, has been solved by Demarcay, Schuster and Hemsalech, who have proved that practically all the "air lines" of a spectrum may be eliminated by placing in the discharge circuit a proper amount of inductance. In this manner the discharge is prolonged and is made to resemble that of the arc.

The electrodes are connected in series with an inductance I , and in parallel with a capacity

FIG. 2.—Circuit for spark discharge. Illustrates a typical discharge circuit. T is an induction coil or high voltage transformer. The primary circuit is operated by a battery, B , or some source of alternating current.

C . Concerning the temperature of the spark very little is known. It has been generally assumed to be very much higher than that of the electric arc; but there is no direct evidence for this view and there is much indirect evidence against it.

3. Separation of Radiations.—Let us suppose that we now have before us one of the above-mentioned sources whose spectrum it is

FIG. 3.—Prism used for examining a point- or line-source. [This figure is taken from Crew's 'Elements of Physics,' published by Macmillan Co., New York.]

desired to examine. The next step will be to separate the rays of various wave-lengths so that we may examine them independently. The reader may here assume that each different substance introduced into the flame or arc gives a different spectrum, peculiar to itself; for this is the experimental basis of spectrum analysis. This analysis is usually accomplished either by passing the light through a prism or by allowing it to fall upon a diffraction grating.

The Prism Spectroscope.—If the source of light be small and if it is necessary to make only a hasty visual examination, the most convenient plan is simply to view the source through a prism, placed immediately in front of the eye, as indicated in Fig. 3.

This is an especially useful method in observing the discharge in the capillary portion of a vacuum tube. The chief difficulty in the naked prism is that the source, however small, is generally still so large that the successive colored images formed by the prism will overlap each other, leaving the separation incomplete. To avoid this difficulty a small telescope—called a collimator—is placed between

FIG. 4.—Diagram of spectroscope.

the prism and the source as shown in Fig. 4. In the principal focus of its objective is placed a narrow, straight slit with movable metal jaws. The source is now placed immediately back of this slit, or the image of the source is focused upon the slit by means of a lens, called the image lens.

When the slit is properly placed and illuminated the collimator will emit from each point of the slit a beam of nearly parallel light whose

cross-section is equal to the effective aperture of the objective. If now this emergent beam be examined through a prism and the naked eye as before, a series of colored images of the slit will be seen, each appearing to be at an infinite distance from the observer; and if the slit is narrow these images will be sharp and fine and easily separated. But they will not, in general, appear very bright because the aperture of the human eye is too small to admit more than a fraction of the emergent beam. Accordingly these colored images, each at an infinite distance, are viewed through a small astronomical telescope, called the view telescope. This serves to condense the entire beam which emerges from the prism and reduce it to another parallel beam just large enough to fill the aperture of the average human eye.

FIG. 5.—The spectrograph. [This figure is taken from the optical catalogue of Steinheil in Munich, Germany].

When it is desired to photograph a spectrum the view telescope is removed and is replaced by a camera with a photographic objective. Such an instrument is known as a spectrograph and an excellent modern form of it is illustrated in Fig. 5.

When the typical spectroscope, represented in Fig. 4, is provided with a graduated circle, and so arranged that the view telescope and the prism can rotate about the axis of the divided circle, the instrument is known as a spectrometer, and can be employed for the measurement of prism-angles and wave-lengths as well as for the examination of spectra. In this type of spectroscope it is nearly always necessary for the sake of good definition to place the prism in such a position that it will produce a minimum deviation in the incident pencil of rays. For it is proved in geometrical optics that a homocentric pencil will remain homocentric after passing through a prism only provided the prism is placed in its position of minimum deviation. If the prism be set in any other position the image of a point-source will not be a point, but a line.

Resolving Power of a Prism.—If one had a prism spectroscope which was practically perfect so far as all the optical parts are concerned, he would yet find that the ability of the prism to separate light-waves of different lengths was subject to still another limitation—a limitation which arises ultimately from the fact that light-waves have an appreciable length. This ability to separate radiations is known as “resolving power” and is measured by the ratio $\frac{\lambda}{\delta\lambda}$ where $\delta\lambda$ is the difference of the wave-length and λ the mean wave-length of two spec-

tral lines which can just be resolved by the dispersion piece in question.

Rayleigh has proved that a prism can just resolve two lines when the difference of their refractive indices $\delta\mu$ is given by the following equation $\delta\mu = \frac{\lambda}{l_2 - l_1}$ where l_2 and l_1 are the

thickness of glass traversed by the extreme rays on either side of a parallel beam passing through the prism.

If now $\delta\mu$ be expressed in terms of $\delta\lambda$ by means of a dispersion formula such as the following, due to Cauchy, we have

$$\mu = A + \frac{B}{\lambda^2}, \text{ and } \delta\mu = \frac{2B\delta\lambda}{\lambda^3}$$

where A and B are constants depending upon the kind of glass employed in the prism.

From these it follows that the resolving power, R , for prism is

$$R = \frac{\lambda}{\delta\lambda} = \frac{2B(l_2 - l_1)}{\lambda^2}$$

This equation is fundamental in describing the spectroscopic value of a prism. It means that the resolving power varies directly as the width of the prism and inversely as the cube of the wave-length of the light examined. It tells us also just how thick a prism of any given glass must be, at its base, in order to separate two lines having a given difference of wave-length. The prism spectroscope was first effectively used by Fraunhofer (1817–28); but it was not until 1859 that Kirchhoff and Bunsen demonstrated the power of the instrument in chemical analysis, and in a study of the sun's physical condition.

The Grating Spectroscope.—So far as its auxiliary parts are concerned this piece of apparatus is very like the prism spectroscope: but as regards its essential feature, the dispersing piece, the two instruments are radically different. For the dispersion which is produced by a prism rests ultimately upon the fact that waves of longer length travel through glass at a higher speed than those of shorter length: while the dispersing effect of a grating is due to the fact that when waves of different lengths are forced to pass through a narrow opening, they are all spread out like a fan—diffracted—the longer waves being more spread out, however, than the shorter ones. If a gas flame, turned low, or an incandescent electric lamp be examined through a single narrow slit in a visiting card, a number of spectra will be seen on each side of a central bright image. These have been called, by Fraunhofer, “spectra of the first class.” They are *not* used in spectroscopy. If, however, the same source of light be viewed through two or more fine parallel equidistant slits, placed close together, say less than one-sixty-fourth inch apart, another series of spectra will be observed. These are the combined effect of light passing through several openings; they are known as “spectra of the second class” and are practically the only ones in the grating spectroscope. These narrow equidistant parallel slits were first prepared by Fraunhofer (1821) who formed them by wrapping fine wire over the thread of two parallel screws, then soldering the wires to the screws and cutting away one entire side of the little cage thus formed. Such a device he called a grating. The modern grating is made by ruling straight lines with a diamond point on a flat plate of highly polished

speculum metal. Good gratings have usually from 5,000 to 20,000 lines per inch. Here the light is reflected from the unruled surface between two successive furrows made by the diamond; and diffraction occurs exactly as if the light had passed through a narrow aperture of the same width. Such a device is called a reflection grating, and when placed where the prism stands in an ordinary prism spectroscope we have what is called a grating spectroscope.

When a beam of parallel rays emerges from the collimator and falls upon a grating placed with its rulings parallel to the slit of the collimator, part of the light is reflected according to the laws of ordinary reflection and forms, in the focal plane of the view-telescope, what is known as the central image. The remainder of the light, however, is spread out on either side of this central image, the blue light being deviated least and the red light (longest waves) being deviated most. Unlike the prism the grating yields several spectra distributed on each side of the central image.

If monochromatic light be viewed with such an instrument a series of bright lines—sharp maxima—each an image of the slit will be seen distributed on each side of the central image. The image nearest the central one is said to be of the "first order," the next of the "second order," etc. The properties of these images and of diffraction spectra, in general, are most briefly described by the following three equations, which follow directly from the wave theory of light

$$(a + b) (\sin i + \sin \theta) = m \lambda \dots (\text{Eq. A}).$$

Here $a + b$ is the distance between corresponding points on two consecutive rulings—the so-called grating constant. The angle of incidence is denoted by i ; the angle of diffraction by θ ; the order of the spectrum by m and the wave-length by λ . This equation tells us exactly in what position, θ , we must set the view-telescope in order to observe a line of any given wave-length. Conversely it enables us to compute the wave-length when once we know the grating constant and the directions of the incident and diffracted rays.

$$I = I' \frac{\sin^2 \frac{n\mu(a+b)}{2}}{\sin^2 \frac{\mu(a+b)}{2}} \dots (\text{Eq. B}).$$

Here I is the intensity of the spectrum of a monochromatic source of wave-length λ in any given direction, produced by a grating which has n lines ruled upon it at a uniform distance, $a + b$, apart.

I' is the intensity which a single aperture would give in the same direction. The "given direction" is here defined by μ whose value is

$$\mu = \frac{2\pi}{\lambda} (\sin i + \sin \theta)$$

the symbols having the same meaning as in Eq. A.

It is important here to observe that Eq. A. merely defines the direction in which I of Eq. B reaches its principal maxima.

Lord Rayleigh has shown that the resolving power of a grating, R , is defined by the following simple expression:

$$R = \frac{\lambda}{\delta\lambda} = mN \dots (\text{Eq. C})$$

where N is the total number of rulings on the

grating and m is the order of spectrum employed.

All of the best gratings of the world up to the present time have been ruled on Rowland's dividing engines at Johns Hopkins University. After Rowland's death, in 1901, his two ruling engines were not again used until Dr. J. A. Anderson took up this work in 1910. Most of these gratings are ruled with from 5,000 to 20,000 lines per inch; some of them have a ruled surface six inches in width, thus giving a resolving power of no less than 400,000 in the fourth-order spectrum. Such a resolving power is far in excess of anything attainable with prisms of practicable size. Dr. J. A. Anderson, and others, have recently devoted much attention to the problem of securing replicas, or reproductions, of the expensive Rowland gratings. The attempts thus far are full of promise, and if they become wholly successful it will be possible for the physicist and astronomer to secure this fundamentally important part of his apparatus at a cost which will be comparatively only a nominal one.

Concave Grating Spectroscope.—Recent advances in spectroscopy are due in a very large degree to the invention of the concave grating by Rowland in 1883. The distinguishing features of this instrument are that it requires no collimator and no view-telescope, and that it gives spectra which are normal throughout a large range. The ruling is upon a concave spherical mirror of speculum metal, the distance between the lines being equal when measured along a chord. It was with a spectograph of this type that Rowland and Higgs each prepared his superb atlas of the solar spectrum. The same kind of grating was also employed by Kayser and Runge in their profound study of the spectra of the elements.

The Echelon Spectroscope.—Measured by resolving power, the Echelon, devised by Michelson in 1898, is still a more effective instrument. This is essentially a grating with only a few rulings in which the form of the groove is under perfect control. This result is obtained by using a pile of plane parallel plates of equal thickness, the edge of each plate being slightly displaced over that of its preceding neighbor. The high resolving power is obtained by use of spectra of high orders, even as high as several thousand. The Echelon is especially adapted to the separation of the close components of a spectral line, as in the case of the Zeeman effect.

The Interferometer.—Another device for separating the close compound of what is ordinarily called a single spectral line is the interferometer, which is also largely due to Michelson. It is this invention which makes it possible to use the wave-length of the red cadmium ray as a standard of length instead of the international metre at Paris; for Michelson has shown that by the interferometer he can measure wave-lengths with an accuracy of one part in a million.

4. Methods of Recording Radiations.—Having separated the different lines in any spectrum, the next step, in general, is to record the intensity, position (wave-length) and physical character of each of these. Just how this is accomplished will depend partly upon the portion of the spectrum under examination and

partly upon the purpose of the work. If the physical character of a line be the matter in question, a glance of the eye may be sufficient to determine it, or it may require an elaborate investigation by means of the interferometer, according to the detail and accuracy required. To record the position of a line within one Angstrom unit is ordinarily the work of a few minutes; but to measure a wave-length with an accuracy of 0.01 Angstrom unit demands skill of the highest order and plenty of time. In general, however, it may be said that in the ultra-violet region, say from 24,000 to 21,000 photography is practically the only available means for obtaining a record. In the visible portion, say from 28,000 to 24,000 the eye and the photographic plate are each available. By photography Abney has recorded wave-lengths as great as 27,000 Angstrom units.

In the infra-red region, that is for wave-lengths greater than 8,000, the bolometer, the radiomicroscope, the radiometer and the linear thermopile have all been used to good purpose. Rubens employing a linear thermopile has pushed his measures to 261,000. But photography is probably more used than all other methods put together.

5. Comparison and Interpretation of Radiations.—Let us suppose that the lines in the spectrum of a certain body have been analyzed and recorded, it may be only for the moment upon the retina of the eye, it may be permanently upon a photographic plate. The next step is to apply this information to the purpose for which it was obtained. To this end, the observer generally makes one of the five following comparisons:

(a) A comparison of the spectrum in question with itself when the radiation is produced under different conditions. Thus by comparing the ordinary spectrum of the sodium flame with that of the same flame in a strong magnetic field the Zeeman effect was discovered. By comparing spectra of the same star taken at short intervals of time Pickering discovered a new class of double stars called "spectroscopic binaries."

(b) A comparison of the spectrum in question with the spectra of other bodies. Thus a spectrum of iron, placed alongside of solar spectrum of the same scale, convinces one that there are many lines in the two spectra which coincide in position; and that, therefore, iron is probably one constituent of the sun.

(c) A comparison of the spectrum in question with some spectrum predicted by theory. Thus Keeler established Maxwell's view of the constitution of Saturn's rings by comparing the spectrum of these rings with the spectrum predicted by Doppler's principle.

(d) A comparison of the spectrum in question with the same spectrum recorded in other ways. Thus Lewis compares the infra-red spectra of sodium as obtained from the photograph, the phosphorograph, the bolometer, the radiomicroscope, with that predicted by Kayser and Runge's formula.

(e) A comparison of the spectrum in question with a standard scale of wave-lengths, that is, with an ideal spectrum in which each line differs from its nearest neighbor by exactly one Angstrom unit. The most beautiful examples of this comparison are to be found in the maps of the solar spectrum prepared by Rowland and by Higgs.

Concerning the interpretation of spectra, it must be frankly admitted that this is the most difficult part of the entire subject, demanding as it does wide experience in the laboratory and judgment of the highest order. Apparently no theory is so fanciful but it may find some support among the varied and complex phenomena presented by the spectroscope. The science of optics is controlled by a well-established theory, while spectroscopy must still be classed as an almost purely empirical science.

6. Summary of Principles.—There are,

however, some general principles which have been fairly well established. Following are the more important ones:

Spectra of Gases.—The emission spectrum of a gas can be obtained, in general, only by passing an electric current through the gas. The emission spectrum of a gas is practically always a spectrum of bright lines. The emission spectra of solids and liquids are practically always continuous. As illustrating exceptions to this general law may be cited the fact that Paschen using the bolometer has obtained the characteristic radiations of carbonic acid gas heated by streaming through a hot platinum spiral; also the fact that the spectra of gases under very high pressures become nearly continuous.

Kirchhoff's Law.—Let us denote by H the amount of radiant energy, say heat or light, of any one wave-length which falls upon a body at temperature t° in one second. Let h denote the energy of the same wave-length which this body absorbs in one second when at the same temperature. The ratio h/H is what Kirchhoff calls the "absorption" of the body, and is denoted by A . A body which absorbs all the heat falling upon it is said to be "absolutely black"; its absorption is unity. Let us now denote by E the amount of energy of the same wave-length which this same body would radiate in one second. This quantity is called the "emission" of the body. Now Kirchhoff, in 1859, proved that:

(1) The ratio of the emission to the absorption of any body depends upon the temperature only; and

(2) This ratio is numerically equal to the emission of an absolutely black body at the same temperature.

By means of these two general principles Kirchhoff was enabled to explain the fact that a sodium flame placed between one carbon pole of an electric arc and the slit of the spectroscope will produce two dark absorption lines in the orange of the continuous spectrum exactly where, without the arc, it would produce two bright lines. But what is more important, Kirchhoff succeeded in explaining, on these same principles, the dark lines which Fraunhofer mapped in the spectrum of the sun. The continuous part of the solar spectrum is supposed to be due to the bright, underlying layers of the sun, which are under great pressure; while the dark lines—the so-called Fraunhofer lines—are due to absorption of the cooler gases which surround the sun. In the same manner may be explained the dark lines which appear in several classes of stellar spectra.

Doppler's Principle.—If we denote by v the speed with which any radiant source is approaching the observer, by V the speed of light, and n the number of waves of length λ emitted per second by the source, then it is evident that the n vibrations which the source emits in any one second will be distributed over a distance numerically equal to $V-v$. Hence the wave-length of the light, λ , which reaches the observer will be

$$\lambda = \frac{V-v}{n} = \frac{V}{n} \left(\frac{V-v}{V} \right) = \lambda_0 \left(\frac{V-v}{V} \right).$$

It is evident, therefore, that the wave-lengths of light coming from a star which is approaching

the observer will be shortened in the ratio $\frac{V-v}{V}$. In like manner, if a star be receding

from the spectroscope the wave-lengths will be increased in the ratio $\frac{V+v}{V}$. This principle,

first enunciated by Doppler in 1843, enables the astrophysicist to measure rates of approach and recession. Recent work by Frost and Adams shows that the speed of a star in the line of sight can be determined with an error not exceeding one-half mile per second. In like manner the relative motion of the two limbs of the sun and of several of the planets, and hence their periods of rotation, have been determined by the spectroscope. Even in the very faint spiral nebulas, the rotation and the nature of their motions in space can in some cases be found, thus throwing a flood of light on the nature of these bodies and on the possible development of stars from them.

Effect of Pressure.—In 1895 it was proved by Humphreys and Mohler, from measurements made in the physical laboratory of Johns Hopkins University, that the wave-length of a line in the spectrum of any element is dependent upon the pressure of the medium surrounding the source. Thus when the cadmium arc is worked under a pressure of 10 atmospheres the cadmium lines are shifted toward the red end of the spectrum about 0.07 of an Angstrom unit. In general, the amount of this shift is toward the red, directly proportional to the wave-lengths in any one element, and directly proportional to the excess of pressure above one atmosphere.

Effect of Atmosphere Surrounding Source.—It has been shown by Crew, Basquin, Porter and Hartman that the spectrum of an electric arc between two metallic electrodes is very distinctly affected by surrounding it with an atmosphere other than air. In the case of hydrogen, it has been shown that the lines affected by the hydrogen atmosphere belong to the spark spectrum of the metal. It is also true that the lines which belong to Kayser and Runge's series are not affected by the change from air to hydrogen. It has been suggested that this effect may account for the peculiar spectra of many of the so-called "hydrogen stars," that is, stars in which the hydrogen spectrum is very strong.

The Zeeman Effect.—In 1896 Zeeman, then at Leyden, made the capital discovery that if a source of radiation be placed in a magnetic field each individual line in its spectrum will in general become a triplet with the two side components circularly polarized and the middle component plane polarized.

Temperature Effects.—The rôle which temperature plays in the production of line spectra is very little understood. It is, at present, impossible to say to what extent the various characteristics of flame, arc or spark, spectra depend upon temperature, upon chemical action and upon electrical conditions. But in the case of solid bodies, which yield a continuous spectrum, Stefan showed, in 1879, that the total radiation varies as the fourth power of the absolute temperature. And it has since been established by Wien that, if we denote absolute temperatures

by T , $\lambda_m T = \text{constant}$ and $I_m = T^3 \text{ constant}$ where λ_m indicates the wave-length at which the radiation is a maximum and I_m represents the value of the maximum radiation. These two important laws are merely inferences from a still more general expression which Wien has established.

Law of Spectral Series.—Soon after the discovery was made that there exist in the spectra of the elements certain series of lines distinguished by certain common characteristics, Balmer succeeded in devising a single formula which gives, in a very exact manner, the wave-length of each of the hydrogen lines known to him at that time. The expression is as follows:

$$\lambda = \lambda_0 \left(\frac{m^2}{m^2 - 4} \right)$$

where λ_0 is a constant and m denotes the natural numbers beginning with 3. This formula has since shown itself competent to describe accurately the 29 hydrogen lines which are now known.

In 1888 Kayser and Runge began a remarkable study of the arc spectra of many of the more important elements and showed that most of these elements contain one or more series of lines capable of representation by the following formula:

$$\frac{1}{\lambda} = A + B_{m-2} + C_{m-4}$$

in which A , B and C are constants for each series, and m denotes the natural numbers beginning with 3. Each different chemical element has its own different characteristic values for these three constants. This fact is the foundation of spectrum analysis.

Rydberg has shown that the following expression is equally effective in representing the facts:

$$\frac{1}{\lambda} = A + \frac{B}{(m+\mu)^2}$$

where A , B and μ are constants for each series, while λ and m have their previous meanings. Thus in the case of Mg , Zn and Cd there are six such series, in each case equivalent to two series of triplets. It is to be hoped that this great advance will be followed some day by a dynamical explanation of the vibrating atom, which will include these two formulæ as rigidly derived inferences.

Bibliography.—In the way of general treatise, consult Kayser, 'Handbuch der Spectroscopie' (Leipzig 1900), as incomparably the most complete and scholarly work in existence. Here may be found references to the literature of every part of the subject. For a complete theory of the plane grating consult Rowland, 'Physical Papers.' A most elegant and simple theory of the concave grating is given by Runge in Kayser, 'Handbuch der Spectroscopie.' On the general theory of the spectroscope consult a series of papers by Wadsworth in the 'Astrophysical Journal,' Vol. I *et seq.* An excellent treatise on stellar spectra is Scheiner, 'Astronomical Spectroscopy,' translated into English by Frost (1894). Solar spectroscopy is treated by Young in 'The Sun' (International Scientific Series) and by an important series of papers by Hale running through the 'Astrophysical Journal' from its beginning up to 1916. A very large number of additional papers

of value will be found in the 46 volumes of the last-named publication.

HENRY CREW,
Professor of Physics, Northwestern University.

SPECTRUM ANALYSIS. See SPECTROSCOPY.

SPECULARITE. See HEMATITE.

SPECULUM. (1) *In optics and astronomy*, a polished surface usually made of a metallic alloy that admits a high polish and resists corrosion and formed either flat or curved, for reflecting images. Specula are employed in large telescopes as reflectors. (See TELESCOPE). (2) *In medicine and surgery*, an instrument for opening a part or passage of the body, especially for dilating an orifice, and introducing a reflector, so that in combination with a light the interior can be viewed. It is used to facilitate examinations and operations.

SPECULUM METAL. See MIRROR.

SPEDDING, spĕd'ing, **James**, English editor and author: b. Mirehouse, Cumberland, 26 June 1808; d. London, 9 March 1881. He was graduated from Trinity College, Cambridge, in 1831, was long an honorary Fellow of his college, from 1835 till 1841 was employed in the Colonial Office and in 1842 was secretary to Lord Ashburton's mission to the United States for the settlement of the north-west boundary dispute. On the formation of the Civil Service Commission in 1855 he became its secretary. In 1847 he undertook, with the collaboration of R. L. Ellis and D. D. Heath, to prepare a complete edition of Bacon's works; but the former died while the task was unfinished and the latter only gave occasional assistance. The work, therefore, was almost entirely left to Spedding, who completed and published his labors in seven volumes (1857-59). This done, he published 'The Life and Letters of Bacon' (1861-74); 'Reviews and Discussions, Literary, Political and Philosophical, Not Relating to Bacon' (1879); and 'Studies in English History' (with J. Gairdner, 1881). Leslie Stephen has called Spedding's Bacon "an unsurpassable model of thorough and scholarlike editing." Consult the 'Life' by Venables appended to the edition (1881) of 'Evenings with a Reviewer,' privately printed by Spedding in 1845 and republished (London 1881).

SPEE, Maximilian, COUNT VON, German admiral: b. Copenhagen, Denmark, 1861; d. off Falkland Islands, 8 Dec. 1914. He was one of Germany's leading naval strategists and was credited with a prominent part in perfecting the plan by which in case of war the scattered warships of the German navy were to assemble. The plan went automatically into effect upon the outbreak of the European War, and the command of the fleet thus gathered fell to Von Spee. He surprised and defeated the British squadron under Admiral Cradock off Coronel, Chile, 1 Nov. 1914. He was in turn attacked and his fleet destroyed by a British fleet under Rear-Admiral Sir Frederick Sturdee off Falkland Islands, 8 Dec. 1914. Von Spee went down with his flagship, the *Scharnhorst*.

SPEECH, the production of articulate sounds by the voice organs; it consists in tones of voice modified by the agency of the tongue,

cheeks, lips and other structures intervening between the glottis and the outer opening of the mouth. The modifications of articulate sounds which may be invented and used by man are almost without limit; the modifications actually used in the ordinary speech of all mankind numbers at least a thousand, and a universal language would have to provide symbols representative of that many speech sounds. Nevertheless, the number of distinct sounds in any one language seldom exceeds 50. In English speech two classes of sounds are produced, known as vowels and consonants. Vowels are pronounced by sounds coming primarily from the larynx; consonants are formed by sounds due to interruption of the currents of air in the mouth or passages above the larynx. The name consonant denotes a sound that cannot be produced effectively without the aid of a vowel. The vowels are further distinguished by the fact that they can be sounded mutely, or in a whisper. The differences between vowel sounds are owing to differences in the dimensions of the space between tongue and palate (mouth cavity) and of the mouth opening, when the vowels are pronounced, as shown in the following table:

Vowel	Sound	Size of mouth-opening	Size of mouth-cavity
a	as in <i>far</i>	5	3
e	as in <i>vein</i>	4	2
i	as in <i>marine</i>	3	1
o	as in <i>cold</i>	2	4
u	as in <i>moon</i>	1	5

Vowels sounds can be prolonged indefinitely; so may some consonants, as l, m, n, r, s, z, etc.; but others as b, p, t, d, k, g hard, cannot be prolonged. Absence of the sense of hearing prevents the perception of sounds and also their imitation—hence persons born deaf are necessarily dumb, but through training such persons may acquire the power of speech. Where dumbness exists without deafness the affection is due to some disorder of the nerve centres. See LANGUAGE, SCIENCE OF; VOICE AND VOICE CULTURE.

SPEECH, Defects of. Speech is an extremely complex and intricate mechanism, and in the normal adult represents a large number of various factors. Its defects, therefore, are equally complex. In ordinary speech at least three separate types of processes are involved: (1) sensory; (2) motor, and (3) intellectual or associational.

(1) The sensory mechanism of speech includes all the avenues by which the idea of a verbally expressible picture can get into the brain. The eye and the ear are mostly used because with these senses the pictures are most distinct, but touch, smell or other sense, if recognized, may be of use in the faculty of speech. Thus with the sensory portion of the speech-mechanism the intellectual factor must necessarily be joined. One sees the words on a printed page and pronounces them; but if written in a script to the reader unknown, he can see the characters and yet will not be able to utter the sounds they represent.

(2) The motor side of speech implies (a) the ability to use the muscles of speech and (b) the power of co-ordinating those muscles so as to say the right things. The lips, the

tongue, the larynx, the teeth are the organs mostly used in speech. One may say that in deaf-mutes the hands are organs of speech. The nerves that govern the muscles ordinarily used in speech are the motor cranial nerves, the nuclei of which are located in the medulla oblongata (q.v.); but the centre that co-ordinates their movements with the sensory impressions which come in through the organs of special sense, as well as with the intellectual concepts concerning the things seen, heard or touched is located in the third frontal convolution or Broca's convolution. This is the chief motor centre for speech.

(3) The intellectual factor in speech implies the action of co-ordinating and associational fibres in the human brain that pass from the sensory centres to the motor centres. It is the factor that governs, as it were, the knowledge of what one is saying. One may repeat from the hearing a line of Choctaw, but without understanding it: the intellectual factor is here non-operative. Memory-images of many kinds may be reproduced by appropriate stimuli; and defects in certain parts of the brain interfering with the bringing out of the memory-images by which a sound is associated with its cause, or an object with its name, occasion certain well-defined disorders of speech. The act of speaking, therefore, requires: (a) the power to think or to construct an idea; (b) the capacity to recall and to formulate the word or words which express the idea; (c) the ability to artic-

ulate the sounds in an understandable or conventional manner.

It is customary to use the word aphasia to denominate true defects of speech. Defects in the incoming sensory tracts, which must modify speech in some respects, are not usually included in this category. In the same manner defects in nervous supply of the muscles of speech, such as paralysis of the tongue, are not termed aphasia. Again, a purely intellectual defect, as in idiocy, whereby speech is seriously affected, is not classed as aphasic. Seglas has divided the disorders of speech into three groups: (1) dylogias, or the disorders of intelligence which affect speech—as seen in idiots, imbeciles, etc.; (2) dysphasias, or true affections of speech (aphasias)—the most interesting and complicated; (3) the dysarthrias or the disorders of articulation—such as are seen in stuttering, in the peculiar speech of deaf-mutes, in the speech of bulbar palsies, of facial paralyses, etc.

The aphasias are the defects of speech that involve the association-tracts and the sense-centres and have been most exhaustively studied. Speaking generally, the true aphasias may be classed in three broad groups: (1) the receptive or sensory aphasias, which result from some injury to the centres for sense-memories of things heard, seen, smelt, tasted, touched, etc.; (2) the conduction-aphasias, which follow injury to the conducting fibres in the brain that pass from a sense-centre to

CHART.—(FROM LANGDON, 'APHASIA').

APHASIA	Receptive, or "Sensory"	Auditory aphasias	1. Amnesia verbalis (word deafness), the non-recognition of word sounds.
			2. Amusia (music deafness), non-recognition of musical sounds.
			3. Auditory apraxia (object deafness), non-recognition of object sounds.
			4. Alexia (word blindness), non-recognition of word meanings.
			5. Visual apraxia (object blindness), non-recognition of object meanings or uses.
		Visual aphasias....	6. Visual amimia (pantomime blindness), non-recognition of word or pantomime mimicry.
		Olfactory aphasias.....	7. Cortical anosmia (smell memory loss), non-recognition of objects by smell.
		Gustatory aphasias.....	8. Cortical agusia (taste memory loss), non-recognition of objects by taste.
		Myotactic aphasias.....	9. Myotactic alexia (word anaesthesia), non-recognition of word movements by finger or pen.
			10. Myotactic amimia (pantomime anaesthesia), non-recognition of mimicry by touch.
	Conduction, "Associational"	Auditory paraphasia.....	11. Myotactic apraxia (object anaesthesia), non-recognition of objects felt.
			12. Paraphasia verbalis (spoken word forgetfulness), non-recollection of word sounds.
		Visual paraphasia.....	13. Paramusia (musical sound forgetfulness), non-recollection of musical sounds.
			14. Auditory paraphraxia (object sound forgetfulness), non-recollection of object sounds.
			15. Paralexia (word meaning forgetfulness), non-recollection of word meanings.
		Olfactory paraphasia.....	16. Visual paraphraxia (object meaning forgetfulness), non-recollection of object meanings.
		Gustatory paraphasia.....	17. Parosmia (smell memory forgetfulness), non-recollection of smell meanings.
			18. Parageusia (taste memory forgetfulness), non-recollection of taste meanings.
		Myotactic paraphasia.....	19. Myotactic paraphraxia (object touch forgetfulness), non-recollection of feel of objects.
		Concept aphasia.....	20. Myotactic paramimia (pantomime forgetfulness), non-recollection of mimicry movements.
Emissive, or "Motor"	Spoken.....		21. Anomia (name memory loss), non-recognition of names of objects.
			22. Paranomia (name forgetfulness), non-recollection of names of objects.
			23. Psychic motor aphasia (spoken word construction lost), loss of psychic spoken word plans.
			24. Executive motor aphasia (spoken word utterance loss), loss of spoken word motor memories.
	Written.....		25. Psychic agraphia (written word construction loss), loss of psychic written word plans.
			26. Executive agraphia (written word utterance loss), loss of written word motor memories.
	Pantomimic.....		27. Psychic amimia (pantomime construction loss), loss of psychic word mimicry plans.
			28. Executive amimia (pantomime utterance loss), loss of word mimicry motor memories.

the motor centre; (3) emissive or motor aphasia, which is produced by an injury to the motor cortex chiefly of Broca's convolution. Some 30 different types of aphasic disorder of speech are known and may be summarized on the chart here given; but some of the commoner forms of aphasia may be mentioned. Of the receptive or sensory type, amnesic aphasia, or word-deafness, is one of the most characteristic. In all of the sensory aphasias there is a loss of comprehension of the words heard or read. In amnesic aphasia the patient hears very distinctly everything that is said, but it might as well be in a foreign tongue, because of the disorder of the centre for word-memory pictures in the temporal convolution. The patient usually speaks, but makes many lapses, not knowing just what he is saying and on hearing his own speech not understanding it. Many varieties of this defect are known. They should be studied in special monographs (see chart for varieties). In the conduction or association aphasias or paraphasias, the association-fibres connecting one speech-centre with another are interfered with. Any of the types may be present, but the form most often seen is one in which the tracts between the auditory centres and the motor speech-centre is involved. Here the patient is aware of the words, knows what they mean and tries to speak, but speaks incorrectly; his path seems to be blocked. The commoner type is motor aphasia. In this Broca's convolution is affected. The patient here sees and hears and comprehends, but is unable to speak the words. He is likewise unable, as a rule, to write the words he sees or hears, and hence suffers from agraphia as well. Many common expressions, as "yes" and "no," "good-morning," "good bye," etc., may be retained. The mechanical necessities that underlie many intellectual processes are clearly brought out in the study of aphasia; and in no other manner is the knowledge driven home how dependent one is on the proper working of certain centres and tracts, as in the study of the defects of speech. SMITH ELY JELLIFFE, M.D.,
Editor 'Journal of Nervous and Mental Diseases.'

SPEECH, Figures of, deviations from the usual order of words in a sentence or from their common and literal sense. These deviations are employed to give vivacity to language in some form or another. Often comparatively primitive languages are rich in bold and imaginative figures of speech. This is because youth is, in language as in races and men, the period of imagination, the time when the human mind works untrammelled by the restraint of the knowledge of the physical laws of nature. The life of primitive man was

filled with images, passions, personal interests, loves and hates. These images he was continually creating out of his experiences or his want of experience. The moment he departed from the familiar facts and experiences of his life, his childish, untrained mind began to picture things, conditions and results outside the common. This habit of expressing out of the ordinary feelings and conditions of life by out of the ordinary forms of language has remained with the race in its most advanced stages. These figures of speech have been modified and refined; but for all this they still retain much of the boldness of their primitive origin. As the imagery of the more primitive races is always the expression of thoughts and images vividly in the mind, and as it is never forced, it is generally true to the thought itself and to the image which graphically presents it. But this is far from being true of the imagery of more advanced races who have borrowed much from the past, often retaining the form after the cause that called it into being has been forgotten. The requisites of proper figures of speech exact that every comparison should be the result of a real likeness clearly presented in an apparently spontaneous manner. It is a general rule that the more marked the difference between the objects compared the greater the contrast and, therefore, the stronger the effect. As this effect should be practically instantaneous upon those to whom the figure of speech is directed, it follows that, as a general rule, it is best not to specify difference, because these details divert the mind from the sudden effect desired. Every word that truly belongs to a language possesses a denotative and a connotative sense. The former expresses the meaning and uses which good society has given it; the latter presents the atmosphere which clings to words, causing them to express thoughts, ideas and associations apart from their ordinary accepted use. Connotation gives us, very often, our most suggestive and beautiful figures of speech and lends to poetry and rhetorical prose much of their attractiveness and grandeur. In treating of figures of speech it is customary to divide the subject into figures of resemblance, figures of contrast and figures expressing other relations than either of the above. The figures of resemblance include the simile, metaphor, allegory and personification. Those of contrast embrace antithesis and epigram. The third classification includes metonymy, synecdoche, apostrophe, exclamation, interrogation, hyperbole, climax, irony, vision, euphemism, onomatopœia, litotes, parallel, allusion and alliteration. A simile expresses resemblance between things that are different. In the metaphor this comparison is implied but not formally expressed; while in the allegory, which is a story couched in symbolical language, the comparison is expressed much more at length than in either the simile or the metaphor. Personification, on the other hand, attributes life to inanimate things and abstract ideas. By its very boldness it merges the idea of resemblance in the animation of the thing personified. Antithesis, as its name implies, is a figure existing by virtue of the contrast of words employed in a sentence, while an epigram, though based upon contrast, is in-

clined to hide this word-contrast by throwing the force of the contrast upon some general idea of contrast in the statement or situation. An epigram, which formerly signified an inscription on a monument, has come to have the sense of a brief pointed saying, generally in the nature of a proverb. Metonymy, which literally means the employment of one name for another, is expressed by substituting the container for the thing contained, the sign for the thing signified, the cause for the effect or the effect for the cause; while synecdoche substitutes a part for the whole or the whole for a part. Apostrophe, being simply a form of address, is frequently used with other parts of speech, more especially metaphor and personification. It addresses the absent as if present and treats the dead as if they were living, and inanimate things as though possessed of life. Interrogations are frequently used for rhetorical effect rather than for the purpose of getting an answer, and in this case they form true figures of speech. In the same way when an exclamation expresses deep feeling, more especially in a condensed form and unusual order, it presents itself in the form of a figure of speech, because it is so arranged as to powerfully attract the imagination. Hyperbole expresses that things or conditions are better or worse, greater or less than they really are, for the sake of the effect thus produced. It is, therefore, historical exaggeration. A climax presents a series of statements or thoughts in the rising order of their importance. When they are presented in the decreasing order of their importance the rhetorical figure is termed an anti-climax. Irony conveys a meaning contrary to the one suggested by the ordinary sense of the statement. Vision, which frequently accompanies apostrophe and personification, presents scenes as though before the eyes although they are past, or imaginary or absent. Euphemism is the name given to that figure of speech whereby an agreeable presentation is given to something that is in itself disagreeable. Onomatopœia adapts the sound of words to their use and meaning. When a statement is made by denying the opposite of what is affirmed the figure of speech thus employed is called litotes. A parallel is an extended antithesis, which continues the comparison of two similar objects, while allusion simply refers to some familiar event or expression by way of explanation or illustration. Alliteration, which is frequently called a figure of emphasis, is the repetition of the same initial sound in a succession of words. It is frequently used in poetry; but it was more commonly employed in more primitive days of the art than at present. See RHETORIC.

SPEECH, Genesis of, or the Origin of Language.* Of these alternative titles the latter is the broader, since "language" is used of the expressive movements of any part of the body (compare the term *Gesture Language*), while "speech" is applied only to expressive movements of the vocal organs. The term "Genesis" is more appropriate than "origin," because the latter implies that speech proceeded from a condition in which speech did not exist, whereas, go back as far as we may in the evolution of animal life, we shall never find a stage in which all of the essential elements of speech are absent. "Genesis" on the other hand suggests the earlier stages of a long and continuous process of development that eventually led to the present highly complex forms of human speech. The phrase "Origin of Languages" sometimes occurs to express the fact that many languages doubtless arose independently in primitive times. The general problem involves two main questions: (1) What was the genesis of the speech movements? (2) How did the speech movements come to be expressive of thought, i.e., of sensations (ideas) and feeling (emotions)? There is really a third question involved: what is the genesis of the ideas and emotions? While ideas and feelings are thought of not as language but as that which is expressed by language, yet it should be remembered that the sensations of sound, the kinesthetic sensations and the mental pictures written and printed words, all of which are indisputably a part of language, are mental processes of essentially the same type as those other ideas which we usually call thought. As a matter of fact the problem of the genesis of speech has usually been confined to the second of the above questions, the other two being left as preliminary problems to the physiologist and the psychologist. As a matter of fact all three are essentially psychological problems.

It is generally held by psychologists that every emotion and probably every other mental state tends to pass over at once into movement. By virtue of the necessary relationship existing between the mental state and the movement the latter becomes symbolic of the former, i.e., the movement is an expressive movement. The connection between the nervous state and movement is very ancient, or, at least, has very primitive antecedents. The simplest monocular animals, such as the paramecium, which has not even an especially developed nervous system, responds consistently by certain definite movements to certain definite stimuli, and even plants possess irritability: that is, response to environment by movement,—which movement is less in plants than in animals primarily, as it would seem, because their cell walls are more rigid than those of animals. Movements of the speech organs (and speech organs similar to those of man occur in nearly all the air-breathing animals of higher rank than the amphibians) are under the same kind of nervous control as all other muscular movements. As the movements of all animals and even of plants are primarily life-serving movements, it is natu-

* NOTE — Before reading this article, section A of the article, LANGUAGE, SCIENCE OF, should be studied.

ral to suppose that all movements had their origin in responses to environment of such a character as to continue the life process. A plant turns to the light, which is the source of the energy by which it makes its food; the paramecium swims away from a poisoned area in the water and moves toward its food. Perhaps chemical and mechanical laws account for these movements. In the case of the lowest animals that possess lungs and a larynx the power of movement is already very highly developed and specialized and under the control of a highly developed nervous system. All animals that possess a larynx make with it movements which produce air vibrations of a frequency within the range that is appreciable through the ear as sound. Birds and quadrupeds produce loud and complex sounds which appear to play an important part in lives of these animals. Undoubtedly man inherited from his pre-human ancestors the power of producing sounds by the movements of his laryngeal and breathing muscles. The range of sounds which animals are capable of producing with their vocal organs is far greater than has usually been supposed. This fact is fully established in the case of apes, which have been more fully investigated in this respect.

Some scholars have assumed that the cooings, gurglings and musical notes made by infants in such great variety before they learn to speak represent a condition in which primitive man found himself before speech was developed. On the contrary these infant cries are doubtless the outcome of a high state of development of the laryngeal muscles and extensive nervous connections which the child inherited from his parents in whom the power of speech was, of course, highly developed. It would be valuable to know how an infant's vocal movements compare in complexity with those of an ape. Phonograph records could be made of both.

Whether the pre-human was capable of using his speech organs for the expression of thought is a question which we can answer to no fuller degree than we can solve the same question in the case of animals. A fundamental question is whether animals, and, therefore, pre-humans (creatures higher than existing animals and still lower than man) had the capacity to think. (Psychologists who have especially investigated the mental processes of animals believe that the more intelligent animals (rats, for example) perform with their brains all the different kinds of processes that men perform, the chief difference between the animals and men being one of relative complexity rather than one of kind.) The question has often been raised as to whether thought antedated language in the evolutionary process or vice-versa. All that seems positively affirmable on this point is that language (i.e., expressive movements) and intellectual life developed side by side. Neither preceded the other. Indeed the two together form one complex psychophysical process. Ideas and feelings are as inconceivable without expressive movement as is expressive movement without ideas and feelings to be expressed. We may assume that an animal's movements are a fairly adequate expression of his mental life, just as the more elaborate vocal movements of man are a fairly adequate expression of his more

complex mental activities. The problem as to how speech movements (and their resulting sounds) gained meaning has been the subject of very extensive discussion. The problem arises from the fact that, while most expressive movements other than speech and not based upon it contain within themselves some element or elements more or less directly related to the meaning and naturally suggestive of it, in the case of speech movements no such relationship exists except in a small group of onomatopoeic words, in which, however, the relationship is merely secondary, i.e., not between the movement and the meaning but between the sound (which is a secondary product of the movement) and the meaning. For example, neither the movements of the vocal organs which form the word "dog" nor the sounds of the word nor yet the written or printed symbol bear the faintest resemblance to the object signified. Latin *canis*, German *Hund*, French *chien* and Russian *sobaka*, words entirely different in movement, sound and appearance, and likewise bearing no resemblance to a dog, serve equally well. The connection between the movement and the meaning is purely arbitrary. On the other hand a gesture, such as pointing, is universal among men and is intelligible everywhere. Further, when an Indian puts two fingers of one hand astride one finger of the other to indicate a man on horseback, or when he puts his hand over his head to signify white man (i.e., one who wears a hat) the connection is still clear.

Various attempts have been made to account for this arbitrary (associational) connection between movement and meaning. (1) Some scholars bridged the gap by assuming that the Creator implanted the gift of speech in man. This in its literal sense is, of course, absurd. Equally absurd, though not so conspicuously absurd, is (2) another "fiat" view of the case, which assumes that groups of men came together and by deliberate choice selected certain sounds to express certain meanings. Such an act is conceivable only among men who already possess the power of speech. With more justification (as might superficially appear) it has been urged that (3) men imitated characteristic sounds produced by objects in the outside world—the so-called "bow-wow," or onomatopoeic theory. More far fetched is the suggestion that men (4) naturally "rang out" the sound characteristic of an object when struck—the "ding-dong" theory. Others assumed that (5) instinctive cries came to be associated with and hence to symbolize the situation or object which produced them—"pooh! pooh!" theory.

All these theories must be regarded as attempts to conjecture how speech might conceivably have arisen instead of as anything even remotely approaching a scientific demonstration of how speech actually did arise. Against the third theory it may be urged that at best it would account for the origin of but very few words. Furthermore it has been shown that of even this relatively small number of words, some have attained an onomatopoeic character in comparatively recent times, having arisen by changes of movement from words that formerly had quite different sounds, and hence could not be used to substantiate this theory.

In so far as these theories attempt to assign a method of origin to individual words, they are open to the objection that, while we cannot say positively what type or types of thought were employed during primitive, incipient stages of human or pre-human speech, still in all likelihood in these earlier stages (and this seems to hold true of animals also) man had occasion to express only masses of ideas, whole situations as yet unanalyzed into detailed ideas such as are expressed by most modern words. A difficulty of the last theory lies in the relatively small number of emotional cries found in a single individual, unless we include the meaningless cries of children mentioned above, with the consequent objections. The last theory also assumes the existence of speech sounds before thought, which, as was stated above, is as untenable as the converse assumption.

In contrast with these five theories a more scientific attempt to explain the arbitrary connection between speech movements and meaning regards the former, like other gestures, as worn-down remnants of movements that were previously useful (life serving). F. N. Scott (in 'Publications of the Modern Language Association of America') has called attention to a variety of such movements of the speech organs, for example, panting, gasping, grunting, sneezing, coughing, choking, etc. The closing of the glottis necessarily precedes all great muscular efforts of the body. The cessation of such effort is followed by its opening. The necessity of breathing during the strain necessitates gasping. Many such movements occur in typical situations and in accordance with the normal working of the mental processes would soon become closely associated with them.

Movements of the speech organs productive of sound waves occur also in connection with other movements that are life serving. Panting, for example, follows upon all vigorous exercise. The sounds thus produced, through association with the movements which produce them and further with the movements which the latter accompany, become also associated with, and hence significant of, the general situation under which they arise. In the cases mentioned the connection between the two groups of concomitant movements is purely physical. There are, however, other groupings, the connection between which lies in the nervous system. Such secondarily produced movements (whether of the vocal organs or other muscles) are explained by psychologists as due to the "overflow" of exceptionally intense feeling into other nervous channels than those within which they would naturally be supposed to be confined. Instances of such complexes of movement occur in animals. This view provides no final explanation, however, because it at once suggests the question why and how the nervous connection between the two movements arose, i.e., why the overflow took originally the precise channel which it did.

On the other hand there are sound-producing vocal movements which may be instinctive in origin and which are also useful in that they contribute to the survival of the individual and hence of the race. The various calls of animals are of this kind, signifying, as they do, "danger!" "food," etc. Pre-humans doubtless possessed such calls. Assuming that these movements represented in their earlier stages unan-

alyzed general situations, it is easy to see how (as mental powers developed in complexity and the consequent analysis of the general situations brought specific elements into clearer consciousness) the specific dominating elements rather than the general complex came to be symbolized by the vocal movements, thus giving origin to expressions more akin in meaning to the majority of existing words.

In general it may be said that the methods of modern science (as applied both in psychology and in linguistic study) constrain the student of the genesis of speech to confine himself in his search for positive evidence to such linguistic processes as occur in the experience of people now living. This is the only kind of first-hand evidence which can be fully studied by direct examination and which admits of even approximately exact scientific control. Thus the evolutionary processes which are at present taking place form the only safe criteria from which one may draw inferences as to the conditions that prevailed in earlier times. Probably we shall never be able to reconstruct such primitive conditions in detail; we will be limited to the possession of certain general truths concerning their nature. In all study of this subject furthermore one must be continually guided by our best contemporary understanding of the mental processes.

CLARENCE L. MEADER,

Professor of Philology, University of Michigan.

SPEED, James, American politician: b. Jefferson County, Ky., 11 March 1812; d. there, 25 June 1887. He was graduated from Saint Joseph's College, Bardstown, Ky., in 1828, studied law at Transylvania University and in 1833 engaged in practice at Louisville, Ky. He was elected to the legislature in 1847 and as State senator in 1861 he took an uncompromising stand against the proposed secession of Kentucky. Later he was in charge of recruiting stations in Kentucky. He was appointed attorney-general by Lincoln in 1864 and continued in office until 1866 when he resigned to resume his law practice and his professorship in Transylvania University. He served as delegate to the Republican national conventions of 1872-76, but otherwise held no further public office.

SPEED, John, English antiquary: b. Farlington, Cheshire, 1552; d. London, 28 July 1629. He was taught his father's trade of tailoring, and in 1580 was admitted to the freedom of the Merchant Taylor's Company. His earlier occupation aside from the practice of his trade was the drawing of maps, and in 1608-10 he published a series of 54 'Maps of England and Wales.' These reappeared with descriptive texts as Speed's 'Theatre of the Empire of Great Britaine' (1611) and were subsequently issued in several editions. His next work was 'The History of Great Britaine Under the Conquests of Ye Romans, Saxons, Danes and Normans, . . . with the Successions, Lives, Acts and Issues of the English Monarchs from Julius Cæsar to . . . King James.' This work places Speed as the first English historian in distinction from the annalists and chroniclers of preceding times, but in accuracy the work left much to be desired. He published also 'Genealogies Recorded in Sacred Scripture'; 'A Cloud of Witnesses

confirming unto us the Truth of the Histories in God's most Holie Word' (1616).

SPEED, John Gilmer, American journalist: b. Kentucky, 21 Sept. 1853; d. Morristown, N. J., 2 Feb. 1909. He was graduated from the University of Louisiana in 1869, practised civil engineering for a time, joined the editorial staff of the *New York World* in 1877, was its managing editor, 1879–83 and subsequently editor of the *American Magazine* and *Leslie's Weekly*. His publications include 'A Fall River Incident'; 'The Gilmers in America,' and 'A Deal in Denver.' He also edited a volume of the poems of John Keats.

SPEED. See **MECHANICS**.

SPEED AND SPORTING RECORDS.

See **SPORTS: THEIR DEVELOPMENT, SPEED AND RECORD.**

SPEEDOMETER, an instrument for indicating or recording the rate at which a motor vehicle is traveling. It is attached to the dashboard, within easy view of the driver, its mechanism being connected with the front wheels of the car. Improved types indicate not only the speed at which the car is traveling, but register the maximum speed reached and the total number of miles traveled.

SPEEDWELL, a genus (*Veronica*) of annual and perennial herbs and shrubs of the family *Scrophulariaceae*. The 200 species are mostly natives of the north temperate zone; some, mostly shrubby, are tropical or subtropical, and others are Australian. They are found in all kinds of soils, and many are cultivated in gardens for their beautiful white, blue or pink flowers arranged in axillary or terminal racemes. The taller-growing kinds are used mainly as border plants, the dwarfed in rock-gardens; the shrubby kinds are ever-blooming in California. Some of the species were formerly reputed medicinal, and some were used as substitutes for tea.

SPEEDWELL, The, a sister ship of the *Mayflower*, which sailed for Plymouth, but was unseaworthy, and put back to port. See **MAYFLOWER, THE**.

SPEER, spēr, Emory, American jurist: b. Culloden, 3 Sept. 1848. He served in the Confederate army during the last two years of the Civil War; was graduated from the University of Georgia in 1869; studied law, and became solicitor-general of Georgia. He was a member of Congress from Georgia as an independent Democrat, 1879–81 and as Independent 1881–83; he was United States attorney, 1883–85; and was made a United States judge of the Southern District of Georgia in 1885. He was also president of the law department of Mercer University, and an orator of prominence. He is the author of a legal work on 'Removal of Causes from State to United States Courts' (1888), and of 'Lectures on the Constitution of the United States.'

SPEER, Robert Elliot, American religious leader and foreign missions secretary: b. Huntingdon, Pa., 10 Sept. 1867. He was graduated at Princeton University in 1889, later studied at the Theological Seminary there, and since 1891 he has been secretary to the Presbyterian Board of Foreign Missions. He made tours of the foreign missionary fields in China, India,

Japan and Korea in 1896–97; in South America in 1909; and in Japan, China, Siam and the Philippines in 1915. He is widely known in missionary circles as an effective organizer. Author of 'Presbyterian Foreign Missions' (1901); 'Missions and Modern History' (2 vols., 1904); 'Christianity and the Nations' (1910); 'South American Problems'; 'John's Gospel' (1915), etc.

SPEICHER, Eugene Edward, American artist: b. Buffalo, N. Y., 5 April 1883. He studied at the Albright Art School, Buffalo, at the Art Student's League and the Henri Art School in New York, and later studied for two years in London, Paris, Holland, Italy and Spain. He established himself in New York, where he became prominent among the younger artists as a painter of landscapes and portraits. He was elected an associate of the National Academy of Design in 1913 and received the academy's first Hargarten Prize in 1915. He was also awarded a silver medal at the Panama Exposition in 1915. Among his works are portraits of Miss Helen Appleton (Thomas R. Proctor Prize, National Academy, 1911); Charles Dana Gibson (1913); John Nelson Cole (1914); and the landscape 'Morning Light' (Metropolitan Museum, New York 1912).

SPEKE, spēk, John Hanning, African explorer: b. near Ilchester, Somerset, 4 May 1827; d. near Bath, 15 Sept. 1864. In 1844 he entered the army and took part in the Sikh War. During his leave of absence he made hunting and exploring expeditions over the Himalayas and through parts of Tibet, collecting many specimens of animals, plants and minerals. In 1854 he accompanied Sir R. F. Burton (q.v.) and party in an expedition to Somaliland. He next served in the Crimean War, and at its close was invited by Burton to join him in an African expedition, to be carried out at the expense of the home and Indian governments. In June 1858, Speke and Burton proceeded inland from the east coast, their object being to ascertain the position of the great lakes of the interior, confused accounts of which had been from time to time received from the natives. The great lake Tanganika (q.v.) was discovered, and Burton falling sick, Speke proceeded north and discovered the south end of the Victoria Nyanza (q.v.), which he correctly judged to give birth to the Nile. In 1860 he led another expedition, organized by the Royal Geographical Society, which explored the western and northern margin of the Victoria Lake, and found a river flowing out of the lake, which turned out to be the White Nile. After long delays in Uganda and Unyoro the travelers proceeded northward, and at Gondokoro met Sir Samuel Baker, who was leading an expedition southward. Returning home he was killed by the accidental discharge of his gun while out shooting. He published 'Journal of the Discovery of the Source of the Nile' (1863); and 'What Led to the Discovery of the Source of the Nile' (1864).

SPEKE'S ANTELOPE. See **BUSHBUCK**.

SPELLING, orthography, the formation of words by means of letters or alphabetic symbols. In certain languages like Spanish, for instance, the system of representing the sounds of the language by alphabetic symbols is prac-

tically perfect. In other words it is phonetic. In English, on the contrary, the multiplicity of vowel sounds and the composite character of the language itself have, in the course of several centuries of growth and continuous imitations, made of the alphabet a curious complex and complicated patchwork which is the despair of foreigners who attempt to learn the language. A technically perfect alphabet should have an alphabetic symbol to represent each sound in the language and no symbol should represent more than one sound. Were this the case all the difficulty in spelling would at once disappear. In Spanish schools spelling is not taught because of the regularity of the Spanish alphabet. In Italian also there is very little necessity for the teaching of spelling, for the same reason. But the irregularity of the English alphabet has placed a heavy burden upon the shoulders of elementary pupils and of foreigners learning the language. Years of study and practice are necessary to acquire a command of English spelling.

The modern English alphabet illustrates vividly the various changes through which the English tongue has passed since the days when the Germanic tribes first began to overrun the British islands. Saxon, Dane, Northman, Norman French, Celt and Latin have contributed to make it what it is to-day by giving it vowel and consonantal sounds and modifying those it primitively possessed when Saxon and Celt first met on English soil. The English alphabet has grown up without any attention being paid to its development or any effort being made to direct its development or to shape its ends. The result is that English has acquired a great many more alphabetic sounds than it possesses symbols with which to represent them. This, in itself, is bad enough, but the confusion is made all the greater by the fact that sometimes there are two or more symbols to represent the same sound, and that quite frequently compound letters are used to represent simple sounds. How complex, confused and confusing is English orthography may be illustrated by presenting the different garbs under which the sound *c* or *k*, as in cat or kit presents itself. It is represented by *cc* as in account; *cch* in Bacchus; *ck* as in back; *cq*, as in acquaint; *cu* as in biscuit; *lk*, as in talk, chalk; *lke*, as in Folkestone; *q*, as in queen; *qu*, as in liquor; *que*, as in barque, antique; *quh*, as in Urquhart; *sc*, as in viscount; *ugh*, as in hough; and *x*, as in excise, except; and finally by three combinations of the *k* symbol, *k*, as in kite; *ke*, as in Burke; *kh*, as in khan, making, in all, 19 letters and combinations of letters to represent the same sound. As if these various modes of representing the same simple sounds were not confusing enough, some of the combinations are used to represent other sounds. Thus *ugh*, in cough, represents *f*; *ch*, in schism is mute, while in schist it is sounded as *h*. *X*, in anxious has the force of *ksh*, and *ks*, in box. In Kale, Kaiser and words of Greek origin, *k* has the sound usually attributed to its name, and office which betrays its Greek origin (though it came into English from Latin, where it was also used almost altogether in the spelling of Greek words). Such irregularities as the foregoing are abundant in English spelling. The original cause of these

irregularities, was prolific of a good crop of changes from the original Saxon forms of the English tongue. These were multiplied by the constant modifications produced by these various language sources acting and reacting upon one another, by the obscuring of full sounds and by the neglecting of others. These changes seem to have been many and to have taken place rapidly between the time of Chaucer and Shakespeare. The evidence of the cause of many of these changes is still to be seen in England and the Lowlands of Scotland to-day in the various rural dialects which sharply differentiate localities.

Printing and Spelling.—When printing was first introduced into Europe there was no standard of spelling, but attempts at spelling invariably conformed more or less to the sound of the word. As this sound was frequently quite different in different localities the attempts to represent it phonetically produced widely varying results. A similar result may be seen to-day in the conscious attempts of certain British writers to reproduce the Lowland Scotch, Yorkshire, Cumberland, Devonshire and other dialects and of American dialect writers to present graphically the manners of speaking English of the negro, the various foreigners in the country, the New England, Ohio, Western and Southern dialects. As there is no prescribed standard for the representation of these dialects so there is no uniformity of spelling employed by the different dialect writers. This condition represents well the lack of uniformity in spelling among writers of English previous to the introducing of spelling and even for some time afterward. But the multiplicity of books made possible by the invention of the printing press, the vast reduction in the cost of reproduction and the consequent spread of the printed word from the commercial centres made the imposition of some standard of spelling necessary. Unfortunately the imposition of this standard came at a time when the English language was still rapidly undergoing phonetic changes, and the standardized spelling made no provision for the modification of itself in conformity with the changes taking place. The Renaissance brought into the English language many foreign words, generally in their native dress, and these introduced new sounds and letters and combinations of letters, thus adding to the confusion, which became gradually greater as many of these foreign words, in the mouths of the illiterate, were modified in pronunciation while still preserving more or less closely their original spelling. In the course of time these various many-sided influences, syllables and sounds that were pronounced, at an earlier stage of the language, became mute; but still the rules of printing and custom engendered by them retained them. These attempts to promote a certain arbitrary uniformity and accuracy, while beneficial, contributed powerfully to the increase of the confusion already existing, by failing to provide for the recognition of signs becoming mute and of syllables and letters changing their phonetic value. This naturally continued to increase the ambiguity of the phonetic values of the letters of the alphabet and to augment the irregularities in their use. No longer the name or given value of a letter

and its sounds in actual use corresponded. To such an extent has this confusion been carried that there is, at present, not a single letter in the English alphabet that does not represent two or more sound values. The vowels, being the actual voice sounds, are the most irregular in this respect. An analysis of these sounds is most suggestive of the confusion existing in English phonetics. Thus *o* has 10 sounds; *a*, *e*, and *u* have nine each; *i* has eight; while *y* has two as a vowel and three as a consonant. Were these sounds not duplicated they would represent 48 different vowels; but they are constantly replacing one another, thus making confusion more confounded to the foreigner who attempts to learn the English language. The confusion in the use of the consonants is great. One of them, *c*, has six sounds; four, *j*, *s*, *t* and *x*, have five sounds each; three, *d*, *g*, *z*, have four each; six, *f*, *h*, *l*, *m*, *n*, *q*, have three each; and the remaining seven have two each. The confusion in English orthography is still further increased by the presence of a great number of silent letters, some of which, however, serve to determine the value of other letters. There are but 44 sounds in the English language yet they are represented by about 500 symbols and combinations thereof with their various applications.

Phonetic Spelling.—Many attempts have been made at phonetic spelling, and the more scientific of these have come pretty near perfection, the failure to achieve perfection being due, in some cases, to a desire to achieve the practical over the purely scientific and phonetic. The best of these attempts have been made by the writers of methods of shorthand, one of the earliest and most satisfactory of which was that of Isaac Pitman (q.v.), which, with its derivatives, is the most widely used of shorthand systems. Pitman furnished an alphabet of 24 consonant and six long and six short vowel sounds, as follows: Consonants, *p*, *b*, *t*, *d*, *ch*, *j*, *k*, *g* (in *go*), *f*, *v*, *th* (in *thick*), *th* (in *thy*) *s*, *z*, *sh*, *zh*, *m*, *n*, *ing*, *l*, *r*, *w*, *y*, *h*; long vowels *a* (*ah*), *a* (*say*), *e* (*see*), *a* (*all*), *o*, *oo*; short vowels, *a* (*that*), *e* (*men*), *i* (*is*), *o* (*not*), *u* (*much*), *u* (*good*). For this purpose Pitman invented a series of new symbols quite distinct from those of the ordinary Roman alphabet, and he added a series of four diphthong symbols representing the sounds *i*, *ow* (*now*), *oi* (*boy*) and *ou* (*you*). These diphthong symbols and the *sh*, *zh* and the two *th* sounds are but duplications of sounds already expressed by other simple symbols in the Pitman alphabet. The work of Pitman and of some 200 workers in the field of shorthand together with many who have followed in his foot-steps has tended toward the simplification of English spelling to some small degree so far as the actual reforms accomplished. But the work is really greater than it appears, since the moral influence and the example of success attained of shorthand writers are already strongly thrown in the balance for radical and effective spelling reform, the demand for which growing slowly but nevertheless surely. See SHORTHAND; SPELLING REFORM; PHONETICS; INTERNATIONAL LANGUAGE.

SPELLING REFORM, a systematic attempt to represent phonetically by letters in writing and print the accepted pronunciation of words. Such changes as have been made in any of the languages where the attempt has been made are of a purely tentative order. As was to be expected, in view of the power of the French Academy, the greatest advance towards a satisfactory and consistent spelling has been made in the French language, but there remains still much to be done before the written word is as indicative of the correct pronunciation as is the case of Spanish and Italian. In Spanish, spelling is now absolutely phonetic, and Italian leaves little to be desired in this direction. In Germany the first moves toward improvement were made in 1880, the chief features of which were the omission of superfluous signs, the substitution of *f* for *ph*, the determination of the distinction between the hard and soft sounds of *s*, and changes of such nature. Changes in spelling have been continuous in the history of the English language, and conscious and deliberate efforts to simplify English spelling began at least as early as 1554. Dr. Johnson's 'Dictionary,' published in 1755, marked the beginning of the era of uniformity. Previous to this, people spelled as they pleased or as they could, sometimes using two or even more forms of the same word in the same paragraph. Shakespeare is known to have spelled his own name in 30 different ways, and other writers of the times previous and after 1755 were hampered by none, or very slight conventional rules, and were free to spell "like gentlemen," not like pedants. The attempt to reform English spelling, as previously noted, did not begin with Johnson; his work simply marked the place this reform had reached, and set up a common standard. The reform began very early (1554), and it is really no argument against the most advanced propositions to say we are getting away from the language of Shakespeare and the Bible, for if we compare the orthography of the Bible of 1611 with the Bible of to-day, with whose spellings there is no complaint, as many as 116 changes may be found in one chapter, Psalm cvi for instance. The greatest step forward toward a common-sense system was made by Webster in his 'American Dictionary' (1828), but much

as his changes were decried, they were mostly those which had been recommended by others; as for instance, dropping the Norman French *u* (to which the English still cling with their inborn hatred of innovation) from *favour*, *honour*, *colour*, etc., changing the French *metre*, etc., to *meter*; omitting certain double consonants, and instead bringing the spelling of certain classes of words into a uniformity of style—thus making *mould* into *mold*, to agree with *gold*, which had been similarly treated, except in rural Ireland where it is still *goold* (*gould*). The Spelling Reform Association was formed at an international convention held in Philadelphia in 1876; the English association was established in 1879, and in 1884 certain changes were recommended for adoption by both associations as follows:

1. e.—Drop silent *e* when fonetically useless, as in *live*, *vineyard*, *believe*, *bronze*, *single*, *engine*, *granite*, *eaten*, *rained*, etc.
2. ea.—Drop *a* from *ea* having the sound of *e*, as in *feather*, *leather*, *jealous*, etc.
Drop *e* from *ea* having the sound of *a*, as in *heart*, *hearken*, etc.
3. eau.—For *beauty* use the old *beuty*.
4. eo.—Drop *o* from *eo* having the sound of *e*, as in *jeopardy*, *leopard*.
For *yeoman* write *yoman*.
5. i.—Drop *i* from *parliament*.
6. o.—For *o* having the sound of *u* in *but*, write *u*, in *above*, (*abuv*), *dozen*, *some* (*sum*), *longue*, (*tung*), etc.
For *women* restore *wimen*.
7. ou.—Drop *o* from *ou* having the sound of *u*, as in *journal*, *nourish*, *trouble*, *rough* (*ruf*), *tough* (*tuf*), and the like.
8. u.—Drop silent *u* after *g* before *a*, and in native English words, as *guarantee*, *guard*, *guess*, *quest*, *guild*, *guilt*, etc.
9. ue.—Drop final *ue* in *apologue*, *catalogue*, etc., *dema-gogue*, *pedagogue*, etc., *league*, *colleague*, *harangue*, *longue*, (*tung*), etc.
10. y.—Spell rhyme *rime*.
11. *Dubl* consonants may be simplified.
Final *b, d, g, m, r, t, f, l, s*, as in *ebb*, *add*, *egg*, *inn*, *purr*, *butt*, *bailiff*, *dull*, *buzz*, etc. (not *all, hall*).
Medial before another consonant, as *battle*, *ripple*, *written* (*writfn*), etc.
Initial unaccented prefixes, and other unaccented syllables, as in *abbreviate*, *accuse*, *affair*, etc., *curvetting*, *traveller*, etc.
12. b.—Drop silent *b* in *bomb*, *crumb*, *debt*, *doubt*, *dumb*, *lamb*, *limb*, *numb*, *plumb*, *subtle*, *succumb*, *thumb*.
13. c.—Change *c* back to *s* in *cinder*, *expence*, *fierce*, *hence*, *once*, *peace*, *scarce*, *since*, *source*, *thence*, *thierce*, *whence*.
14. ch.—Drop the *h* of *ch* in *chamomile*, *choler*, *cholera*, *melancholy*, *school*, *stomach*.
Change to *k* *ache* (*ake*), *anchor* (*anker*).
15. d.—Change *d* and *ed* final to *t* when so pronounced, as in *crossed* (*crost*), *looked* (*lookt*), etc., unless the *e* affects the preceding sound, as in *chafed*, *chanced*.
16. g.—Drop *g* in *feign*, *foreign*, *sovereign*.
17. gh.—Drop *h* in *aghast*, *burgh*, *ghost*.
Drop *gh* in *haughty*, *though* (*tho*), *through* (*thru*).
Change *gh* to *f* where it has that sound, as in *cough*, *enough*, *laughter*, *tough*, etc.
18. l.—Drop *l* in *could*.
19. p.—Drop *p* in *receipt*.
20. s.—Drop *s* in *aisle*, *demesne*, *island*.
Change *s* to *z* in distinctive words, as in *abuse* verb, *house* verb, *rise* verb, etc.
21. sc.—Drop *c* in *scemt*, *scythe* (*sithe*).
22. tch.—Drop *t* in *catch*, *pitch*, *witch*, etc.
23. w.—Drop *w* in *whole*.
24. ph.—Write *f* for *ph*, as in *philosophy*, *sphere*, etc.

After 1884 the subject of spelling reform did not attract any general attention for more than 20 years in spite of the publication of periodicals devoted to the propaganda, and the occasional outbreak of some enthusiastic votary, but in 1906 the establishment of the "Simplified Spelling Board" gave the reform a vigorous

thrust forward. The board recommended for adoption a list of 300 "simplified spellings" with which to begin the change toward a more scientific literation of the language. This move would probably have attracted no more notice than many of its predecessors, had not President Roosevelt issued an executive order, in August 1906, directing the public printer to use all these spellings in the papers sent out by his office. The Congress, however, would not allow these changes to be made in the papers that came to the members from the printer, and in December the order was rescinded. The rather ill-advised exuberance of some of the advocates of the reform has made it an object of temporary ridicule, but the probabilities are that the really great advantages to be gained will be more and more appreciated, until the work of the reformers produces tangible and enduring results. The practice of isolated individuals may help, but real reform comes slowly and in accordance with reason and the laws of language. The Simplified Board claims that 380 institutions of higher learning and 456 newspapers and periodicals are now using most of the spellings recommended by the Board.

The character of the simplifications proposed is indicated by the following examples:

1. When *ed* final is pronounced *t*, write it simply *t*, where the change will not suggest an incorrect pronunciation, as *askt*, *fixt*, *wisht*, etc.; reducing a preceding double consonant to a single consonant, as *blest*, *kist*, *dipt*, *dropt*, *slept*, etc.; and changing *-ced* to *-st*, as *pronounst*, *rejoist*, *revert*, etc.; but avoid misleading forms like *bakt* for *baked*, *deduct* or *dedust* for *deduced*, etc.
2. Change *ph* to *f* when so sounded as *alfabet*, *fonograf*, *fotograf*, *sulfur*, *telefone*, *telegraf*, etc.
3. Drop *e* final after *-iv* and *-rr*, as *detr*, *troels*, *corr*, *serv*, *deserv*, etc.; also, in the endings *-ile*, *-ine*, *-ise*, *-ile*, *-ive*, unstressed pronounced *it*, *in*, *it*, *in*, as *hostil*, *textil*, *anilin*, *determin*, *engin*, *examin*, *genuin*, *imagin*, *practis*, *promis*, *definit*, *favorit*, *infinit*, *opposit*, *actin*, *comparativ*, *nativ*, *positiv*, etc.; and at the end of *ar(e)*, *hav(e)*, *gis(e)*, *forgiv(e)*, *misgiv(e)*, *liv(e)*; because its normal use after a single consonant is to show that the preceding vowel is long. Hence it is retained in such words as *bore*, *brave*, *mile*, *fine*, *wise*, *polite*, *arrive*.
4. When the digraph *ea* is sounded as in *head* or as in *heart*, use the letter that is sounded and omit the other, as *hellh*, *hevy*, *insied*, *tred*, *waher*, *plesant*, *hart*, *harth*, etc.
5. Substitute *e* for the digraphs and ligatures *ae*, *oe*, *æ*, when not final, as *medieval*, *fenix*, *cyclopædia*, etc.
6. When *ch* is pronounced *c*, drop *h*, except before *e*, *i*, and *y*, as *caracter*, *epoc*, *arcangel*, *meccanic*, *monarc*, *scolar*, *scool*, *stomac*, *temical*, etc.; but *chemist*, *archited*, *monarchy*, etc.
7. Drop silent *h* from initial *rh*, as *rapsody*, *reumatism*, *rubarb*, etc.
8. Reduce *l'* final, after a short stress vowel, to *l*, as *bil*, *dol*, *dril*, *duel*, *fil*, *ful*, *fulfil*, *shal*, *tel*, *wil*, *wilful*, etc.
9. Reduce the double final consonants *bb*, *dd*, *ff*, *gg*, *nn*, *rr*, *tt*, *ss*, to a single consonant, as *eb*, *ad*, *od*, *cuf*, *eg*, *bwn*, *bur*, *whir*, *net*, *bus*, etc.
10. Drop *-me* from *mme* final, as *gram*, *program*.
11. Drop *-de* from *ette* final, as *cigaret*, *coquet*, *etiquet*, *omeld*, *quartet*, etc.
12. Drop silent *ue* final after *g*, as *catalog*, *colleag*, *dialog*, *pedagog*, *synagog*, etc.; except when *g* is preceded by a single long vowel, as in *rogue*, *vague*, *rogue*, etc. *Tongue* spell *tung*, *Milton's* way.
13. For *-ough* substitute *o*, *u*, *of*, *uf*, *ock*, *out*, or *up*, according to the sound, as *tho*, *thru*, *cof*, *enuf*, *hock*, *droun*, *hiccup*, etc. *Plough* spell *plow*.
14. Drop silent *b* final, as *crum*, *lam*, *lim*, *num*, *thum*, etc.; except where its omission would suggest an incorrect pronunciation, as *tomb*, *comb*, etc.
15. Drop *e* from *ey* final unstressed, pronounced like short *y* final, as *abby*, *barly*, *chimny*, *donky*, *gally*, *mony*, *trolly*, *vally*, *whisky*, etc.
16. Substitute *z* for *s* in the verb-suffix *-ise*, as *advertize*, *civilize*, *criticize*, *pauperize*, etc.
17. Change *re* final to *-er*, as *center*, *fiber*, *meter*, *theater*, etc.
18. Drop *u* from *our* final in words of two or more syllables, as *ardor*, *color*, *favor*, *honor*, *labor*, etc.

SPELMAN, Sir Henry, English antiquary: b. Cougham, Norfolk, about 1562; d. London, 1641. He was graduated at Trinity College, Cambridge, 1583, and then attended Lincoln's Inn. He was a member of Parliament in 1597, high sheriff of Norfolk in 1604 and performed several public services for King James I. He was knighted in 1612 and retired to lifelong study, founding, in 1635, a short-lived Anglo-Saxon readership at Cambridge. His writings include 'De non Temerandis Ecclesiis' (1613); his colossal work, 'Glossarium Archæologicum,' of which he published volumes A to L (1626), the remainder being brought out by his son; and the material for his 'History of Sacrilege,' and his works on 'The Councils of the Church' and 'The Tenures of Knight Service' all of which were left incomplete and were posthumously issued.

SPELTER, in commerce, a name frequently applied to zinc, and to an impure zinc used in soldering. A mass of junked zinc articles, likely to contain impurities, is commonly classed as spelter.

SPENCE, spēs, Catharine Helen, Australian novelist: b. Melrose, Scotland, 31 Oct. 1825; d. 3 April 1910. Her parents moved to Australia in 1839; and 20 years later she began working for electoral reform in behalf of which she lectured all over Australia and in the United States and Canada. She was a member of the Children's League from 1888 until her death and of numerous other bodies; and from 1878 onward she wrote extensively for the press. Most of her literary work appeared in *Fraser's Magazine*, *Cornhill*, *Harper's*, *Melbourne Review* and *Victoria Review*. For many years she worked as a journalist on the *South Australia Register*; and at the time of her death she was president of the Effective Voting League of South Australia and vice-president of the National Council of Women.

SPENCE, Francis Stephens, Canadian journalist and Prohibitionist: b. Donegal, Ireland, 29 March 1850. He went to Canada as a youth, and was educated at the Toronto Normal School. He was for a time engaged in teaching, but from 1882 was active as a journalist. He edited successively the *Canada Citizen*, *Vanguard*, the Ontario *Good Templar*, and was managing editor of the *Pioneer*, all publications of moral uplift tendency. He has been active

in general organization work for Prohibition, and in 1886-1907 was secretary of the Ontario branch of the Dominion Prohibition Alliance. In 1911 he became president of the Ontario Municipal Association. Author of 'The Facts in the Case' (1896).

SPENCE, Henry Donald Maurice, English Anglican clergyman and author: b. London, 14 Jan. 1836. He was educated at Cambridge, took orders in the Established Church, and was professor of English literature at Saint David's College, Lampeter, Wales, 1865-70, and rector of Saint Mary de Crypt, Gloucester, 1870-77. He was principal of Gloucester Theological College, 1875-77, vicar of Saint Pancras, London, 1870-86, and dean of Gloucester from the last-named date. Among his many published books are 'Dreamland and History'; 'The Church of England: a History for the People'; 'The White Robe of the Churches of the 11th Century'; 'Christianity'; 'Secrets of a Great Cathedral.'

SPENCER, spēn'sēr, Ambrose, American jurist: b. Salisbury, Conn., 13 Dec. 1765; d. Lyons, N. Y., 13 March 1848. He was educated at Yale and Harvard universities and was graduated from the latter in 1783. He was admitted to the bar in Hudson, N. Y., where he was elected city clerk in 1786. In 1793 he represented Columbia County in the State legislature; in 1795 and for seven consecutive years was State senator; in 1804 became a justice of the Supreme Court, and in 1819 was promoted to be chief justice, which office he resigned in 1823, and resumed the practice of his profession at Albany. He was for some years mayor of that city, and also represented the Albany district in Congress. In 1844 he presided over the National Whig Convention at Baltimore. His energy, resolution and high legal attainments left a permanent impress on the constitution and institutions of New York.

SPENCER, Claudius Buchanan, American Methodist Episcopal clergyman and editor: b. Fowlerville, Mich., 20 Oct. 1856. He was graduated at the Northwestern University in 1881, and was ordained in the ministry in that year. He held pastorates in Michigan and Colorado in 1881-96; edited the *Rocky Mountain Christian Advocate* in 1892-1900; and since 1900 has edited the *Central Christian Advocate* at Kansas City, Mo. He is prominent as a Prohibitionist and in the general organization work of the Church. Author of 'The Blue Flower of Methodism' (1903); 'The Layman' (1912); 'That They May be One' (1915), etc.

SPENCER, George John, EARL, English politician and bibliophile: b. Wimbledon, Surrey, 1 Sept. 1758; d. Althorp, 10 Nov. 1834. He was educated at Harrow and Cambridge, and was elected member of Parliament for the county of Northampton. In 1783 he became the 2d Earl Spencer. In the House of Lords he voted with the Whigs till the period of the French Revolution, when, with some others of the party, he joined the party of Pitt. In 1794-1801 he was First Lord of the Admiralty and in 1806-07 was Secretary of State for the Home Department. Earl Spencer was president of the Roxburghe Club at its origination, and possessed the largest and richest private library in the world. The foundation of his library

was laid in 1789, by the purchase of books in all parts of Europe. It was described by Diben in 'Bibliotheca Spenceriana' (1814). The bulk of this library is now included in the Rylands Library, Manchester.

SPENCER, Herbert, philosopher and exponent of the modern philosophy of evolution: b. Derby, England, 27 April 1820; d. 8 Dec. 1903. His father was a teacher, a Non-Conformist, who was for years a Wesleyan, but who afterward seceded from that religious body and remained to the end of his life somewhat indifferent to outward religious forms, although a deeply religious man. The subsequent tendency of Spencer's philosophy was indirectly, but in a very potent way, determined by the education that his father gave him during his childhood and early youth. It was an education that decidedly tended to quicken his interest in the study of nature, and to develop his powers of independent thought and of inquiry into the nature of things. Furthermore, the Non-Conformist atmosphere in which Spencer grew up strongly tended to cultivate in his mind political liberalism of the type then characteristic of many of the most progressive English minds. In 1837 Spencer began the study of engineering under Mr. Charles Fox, the engineer of the London and Birmingham Railway, then recently constructed. Spencer continued his work in the service of the railway, with some interruptions, until 1841. In 1843 he went to London and engaged in contributing to the various periodicals, and in somewhat varied activities of a miscellaneous sort, until 1850. In 1842 he wrote a series of letters to *The Non-Conformist*—a newspaper then recently established as an organ of the Dissenters. The letters dealt with some principles relating to the influence of legislation upon social processes, and began the train of thought which Spencer later developed in his 'Social Statics.' The 'Social Statics,' his first book, was written between 1848 and 1850, and is characterized by the author himself as "a kind of natural history-ethics." The work especially maintains the doctrine of the right of the individual, and of the necessity for non-interference on the part of the government. The characteristic of Spencer's sociological studies at this time, as contrasted with those of other English liberals who were his contemporaries, was the tendency to base the doctrine of non-interference upon very general considerations derived from natural history and from the study of natural law in general. Society, like the individual organism, is, so Spencer now teaches, the result of a growth, which is subject to determinate natural conditions, which in consequence tends on the whole to results advantageous, in the end, to individuals, while this growth of society cannot be safely interfered with by artificial devices. A generalization of the interests which Spencer thus early expressed led him within the next few years to a study of the processes of growth in nature in their more general aspects. Accepting, almost as soon as he distinctly conceived of it at all, the doctrine that all living forms are the result of natural processes of growth, and are not due to special creation, Spencer was led during the immediate following years to an effort to formulate in general terms the "law of progress," or of development, which he conceived to be common to all such

processes of growth. In 1854-55 he wrote the first edition of his 'Principles of Psychology,' in which he endeavored, first, to characterize in a decidedly novel way the nature and processes of life in general, and then to apply this general formula to the investigation of the development of mind. Life, Spencer now defines, as a series of changes occurring in an organism in such ways as involve "a continuous adjustment of inner relations to outer relations." The mental processes are then defined as a special accompaniment and result of the adjustment in question. Between 1856 and 1860 Spencer, despite considerable interruption through ill health, published a large number of essays in various periodicals, among which the most important are: (1) the four papers which were later brought together in his volume on 'Education,' and (2) a number of essays tending toward the final expression of his general formula for evolution. As both bodily and mental development had now come, in Spencer's mind, to be conceived as subject to universal and common laws, he began to consider the possibility of a system of philosophy in which the general process of evolution should be stated in terms applicable to all kinds of development. The first sketch of this system of philosophy was outlined in 1858; and in 1860 the definitive program of the 'System of Synthetic Philosophy' was written out. The first edition of the 'First Principles,' which constituted the first part of this "system," was prepared between 1860 and 1862, and was issued to subscribers in parts. The second part of the 'System of Synthetic Philosophy,' namely, the 'Principles of Biology,' was issued between 1862 and 1867. In 1867 Spencer recast and reissued his 'First Principles.' Between 1867 and 1870 he developed a new statement of his 'Principles of Psychology' as modified by the further development of his doctrine. The 'Psychology' in its new form was finished by 1872, and formed the third part of the system. The plan of Spencer's system required, next in order, the application of his principles to the study of sociology, an undertaking which proved to require a longer time than Spencer had originally contemplated. In 1872-73, at the instance of Spencer's American friend, Prof. E. L. Youmans, Spencer prepared, as an "extra book"—not a part of the system—a volume for the International Scientific Series, entitled 'The Study of Sociology.' In 1874 the first volume of the 'Principles of Sociology' began to be issued. For this work Spencer had been making, since 1867, and with the aid of secretaries, the elaborate collections of material which were, in a series of years, published under the title 'Descriptive Sociology.' After completing the first volume of the 'Principles of Sociology,' Spencer turned for the time to the beginning of what was to be the last division of his system, namely, ethics, and published, in 1879, the 'Data of Ethics.' The succeeding years, until the completion of Spencer's system in 1900, were principally devoted to the preparation of the second and third volumes of the 'Principles of Sociology,' and to the completion of the 'Ethics.' The 'Descriptive Sociology' continued to be issued until 1881 in parts. From time to time throughout the period of the preparation of the synthetic

Herbert Spencer

philosophy Spencer was interrupted for greater or shorter intervals by ill health. But he nevertheless found time to prepare and to publish a considerable number of essays of a controversial character, relating to his system and to its critics; to contribute also to various topics of current discussion; and his 'Autobiography,' published in 1904, is still another of the evidences of his extraordinary productiveness.

The complete list of Spencer's works, published during his lifetime, in the form which they finally assumed, in so far as he regarded them as worthy of permanent place among his productions, is as follows: First, the 'Synthetic Philosophy' itself, consisting of 'First Principles' (1 vol.); 'The Principles of Biology' (2 vols.); 'The Principles of Psychology' (2 vols.); 'The Principles of Sociology' (3 vols.); 'The Principles of Ethics' (2 vols.). Second, 'Essays: Scientific, Political and Speculative,' definitive edition (2 vols.). Third, 'Social Statics,' revised edition (1 vol.). Fourth, 'The Study of Sociology' (1 vol.). Fifth, 'Education' (1 vol.). Sixth, 'Facts and Comments' (1 vol.). Seventh, 'Various Fragments' (1 vol.). Eighth, 'The Inadequacy of Natural Selection' (1 vol.). Ninth, 'Descriptive Sociology.' The last of these works is, in the main, a collection of material prepared by Spencer's assistants and printed as such, but under Spencer's direction.

In the most general outlines, what is characteristic of the philosophy of Spencer may be sketched as follows: In his theory of knowledge Spencer has many features in common with the classic English empiricism. But this empiricism, in his case, is modified by considerations due to the doctrine of evolution. Knowledge, namely, as he teaches, arises not merely through the experience of the individual, but through the experience of the race so that, in the individual, inherited intellectual tendencies determine the recognition of certain fundamental truths as certain and unquestionable so soon as attention is attracted to the matters which these truths express. Thus, mathematical certainties are based upon a kind of evidence which the individual finds to be absolute and unquestionable, but which the experience of the race has molded into their present forms. In consequence, when we inquire into the foundations of knowledge, we meet with certain assurances, which, in our individual cases, are to be tested by what Spencer calls the "universal postulate," namely, "the inconceivability of the opposite." That is whatever proposition is such that the experiment of trying to conceive its opposite to be true persistently fails is to be regarded as a primal necessity, and is to be accepted as true. If we ask how the human race came to know this proposition to be true, the answer is, through the inherited effects of experience. But if we ask why the individual must accept it as true, the answer is, simply because the opposite is inconceivable. Among the principles thus warranted by the "universal postulate," the principle of the "persistence of force" is prominent. The fundamental principles of ethics have a similar foundation.

Since the ultimate source of our knowledge lies in the experience of the race, it is impossible either by individual observation or by

means of the inherited effects of experience, to fathom the innermost nature of the real world. We can know only the world as it appears to beings with such an organization as the process of evolution has brought to pass in the case of our race. Any effort to transcend the limitations thus established leads into the region of what Spencer calls the "Unknowable." Yet it would be wrong to endeavor to conceive our world as merely a world of phenomena, or of contents of experience, or to accept any form of idealism. For the test of the "inconceivability of the opposite" assures us, as one of the absolute certainties, that a world of genuine reality, transcending all our experience, both exists and is unknowable to us. It is equally impossible to deny (or rationally to doubt) the reality of such a world and to attempt any positive theory as to what its ultimate nature is. Subjective idealism, denying that the unknowable exists at all, is, therefore, according to Spencer, quite unthinkable. But every effort to give a positive account of ultimate reality breaks down by leading us to unavoidable contradictions, such as are involved in attempting to conceive the world in its wholeness, as either finite or infinite, as either caused or uncaused, as either absolute or relative, and so forth.

All such epistemological considerations, however, are for Spencer mere preliminaries. His principal philosophical interest lies on the positive side, namely, in the effort to reduce to unity the laws of the "knowable" world, that is, the laws which govern the phenomena of nature. Such a unification depends, first, upon recognizing the "persistence of force"—a term by means of which Spencer denotes the conservation of energy, as he conceives that fact. In practice, however, Spencer's term "persistence of force" is applied in more various ways than those which are customary in case of the usual doctrine of the conservation of energy. The "persistence of force," used as a principle, guarantees us against accepting miracles, against conceiving anything as occurring counter to strict natural law, against accepting the doctrine of special creation, and so forth. In brief, the doctrine of the persistence of force gives us a view of what may be called the analytic unity of nature, namely, a view of that character which is common to every sort of natural process.

If, however, we turn from the consideration of this most universal aspect of nature to a study of the various types of natural processes which are observable when we consider large masses, or series of natural phenomena, we come hereupon to the principles characteristic of what may be called the synthetic unity of nature, that is, of that unity which appears when we consider the entire lives of organisms, or the histories of races of living creatures, or the history of planets, of solar systems or, in another realm, of societies. These processes which the persistence of force render possible are of two general types. They are, namely, either processes of evolution or processes of dissolution. Evolution occurs when great aggregations, such as have just been mentioned, appear and grow and become organized. The formation of a stellar system, the solidification of a planet, the gradual building up and diversification of the earth's crust, the growth of a

race of animals or of plants, the life history of an individual or of a nation—these are processes of evolution. Dissolution is the reverse of any of these processes. When an aggregate is disintegrated, dissolved or otherwise destroyed, when an organization passes away or disappears, we are, therefore, dealing with dissolution.

Evolution is of course the more interesting of these two processes. It possesses, according to Spencer, two characteristic forms, primary evolution and secondary evolution—the latter being based upon the former, but occurring in less frequent instances, although these instances are very highly interesting and important. The characteristic of the primary evolutions is that they involve “an integration of matter and a dissipation of motion.” Such processes occur when masses of matter cool, contract and solidify—as, for instance, when planets are formed. The processes of secondary evolution are rendered possible by the fact that some of the bodies subject to primary evolution do not merely contract and solidify, but also pass through a stage or a series of stages of their existence, in which they predominantly possess a “plastic” character. “Plastic bodies” are such as are sufficiently free from a close coherence of parts to permit of easy change in consequence of change in their environment, while at the same time these plastic bodies are sufficiently coherent to retain the traces of disturbances which have happened to them. Thus, a mountain range, subject to erosion, not only yields in numerous ways to the action of water and of weather, but retains, in a great variety of ways, the traces of such erosions as have occurred in the past, instead of being swept away at once by a single flood, as a smaller mass might be. Again, a living organism is a plastic body, so full of internal motion, or of stored-up energy, as to be greatly and easily disturbed by its environment, while at the same time it is so far possessed of rigidity in its structure and in its way of responding to external influences, that traces of what has happened to it remain, in great variety, and for a long time, or even throughout the life of the organism. The power of an organism to adjust itself to new conditions, in combination with the power to form and retain habits, constitutes the basis for all the higher development of life. All such powers depend physically upon the characteristics of the “plastic bodies,” and the process of organic evolution is altogether to be described as due to the accumulation of such secondary evolution as these properties of plastic organisms make possible. Since the brain itself, such as any higher animal possesses, is a plastic body, the result of processes of aggregation, and is itself on the way toward a greater solidification (such as occurs in old age), while the brain, during youth and early maturity, is at once extremely sensitive to disturbances and very apt to retain the results of former disturbance—it follows that the entire evolution of the mind, which so far as the mind is knowable, accompanies the development of the brain, is itself to be described in terms of the properties of the plastic bodies.

In consequence of the fact that evolution, so far as it is a process of the knowable world,

is thus a result of “the integration of matter and the dissipation of motion,” and, in case of the secondary evolutions, is a result of the formation of the plastic bodies, it follows that all evolutionary processes must possess certain common features. The primary evolution, otherwise called “simple evolution,” consists altogether of the formation of “coherent aggregates,” such as result whenever bodies solidify and part with their internal energies. The secondary evolution, also called “compound,” includes changes that are due to “differences in the circumstances in the different parts of the aggregate.” The most notable result of these internal differences is a “transformation of the homogeneous into the heterogeneous.” Wherever evolution takes place in a plastic body such increasing differentiation is inevitable, the reason being that the traces of previous changes are retained, and are made the basis of increasing variety, as the traces of new changes are superposed. In the more complex instances of secondary evolution the transition from the homogeneous to the heterogeneous is long continued and extremely complicated. It is exhibited not only in the structure of an aggregate, but in the functions which belong to this aggregate, in case the aggregate is, like a living organism, the seat of a great variety of energies. The increasing complication and differentiation of the functions and habits of a living organism is thus the result of the same kind of process as makes its appearance even in inorganic nature wherever the results of former changes accumulate in a plastic body. Wherever integration and increasing heterogeneity are long continued and important, they are also accompanied by an increasing definiteness of structure and function, which Spencer describes as due to the process called by him “segregation.” Segregation is exemplified wherever the outlines of things grow sharper, wherever the like things of the natural world tend to be grouped near together or the unlike things to be kept apart. For certain natural forces, whose presence in the world Spencer extensively illustrates, are working along with whatever tends to differentiate phenomena and are so working as to tend to sort out, or to segregate, like and unlike things. Such forces are manifest in the case of the formation of geological strata through sedimentary deposits, and in the case of the grouping together of similar organisms in societies, and in large numbers of other instances. Segregation combines with differentiation, and with integration, to characterize the whole evolutionary process.

As has just been suggested, Spencer also applies these principles to explain the laws of social structure and function and to describe the evolution of society, and his especial interest in all these considerations lies in his attempting to make clear the unity of the evolutionary processes, whether organic or inorganic.

The application of the evolutionary formula to the study of psychology has already been in general indicated. Mental functions grow in a way that is precisely parallel to the growth of certain organic structures and functions. Consequently integration, differentiation and segregation can be traced in mental life as well as in organic life. And in so far as the conditions of mental life are knowable at all, these con-

ditions have to be defined in the terms of the same evolutionary formula which apply to plastic bodies in general, that is, to their structure and to their functions. In order to apply these considerations to that study of ethical problems which so early interested him and to the defense of those social doctrines which he so early emphasized, Spencer laid especial stress upon naturalism in ethics, that is, upon the necessity of consulting the natural conditions of organic life in order to define the norms of conduct. Conduct is an evolutionary phenomenon and is to be considered in the light of the general formula for evolution. Conduct, for instance, is a part of the adjustment of the organism to its environment and is to be judged in the light of the laws of that adjustment. That conduct which secures the most perfect adjustment is at once the most acceptable to society, and, by virtue of the conditions under which mind has developed, is in the long run most satisfactory to the individual concerned. For in case of the human organism, the adjustment of internal to external conditions normally occurs in society. Hence such adjustment as keeps the individual in harmony with his social order is conduct of the type favored by evolution. The inherited effects of experience appear in those of our instincts which fit us for harmonious social life. On the other hand, social harmony does not mean social subordination. The goal of social development is a condition of equilibrium in which the individual is as little interfered with by his society as possible, in so far, namely, as interference would involve coercion or restraint. Meanwhile, as this goal is approached, the individual grows increasingly differentiated in his social functions, better adapted to a wider and wider range of social conditions and more definite in his functions.

Notable in Spencer's work has been his attitude toward the problems of past and of contemporaneous religions. The religions of the world are the results of evolutionary processes whose knowable aspect Spencer elaborately discusses in his 'Sociology.' Viewed as to their contents, they have always included efforts to transcend the bounds of human experience, in a word, to transcend the knowable. But in recognizing the existence of an unknowable, the synthetic philosophy, as Spencer maintains, has itself, in a measure, justified one of the deepest religious interests, namely, the interest of finding ourselves in some sort of relation to a power which, inscrutable though it may be, is still ever-present and is the source of all things.

In his 'Essays on Education' Spencer has made prominent the importance of the study of natural science and has emphasized the significance of the sort of training which he himself originally received from his father.

In sum, Spencer was one of the leaders of the age in which the modern doctrine of evolution came into prominence. In his own development he was, until 1860, when he first became acquainted with Darwin, substantially independent of other evolutionary thinkers, at least among his contemporaries. Indirectly and somewhat unconsciously, he was influenced (as Prof. John Dewey has pointed out) by the tradition of 18th century French

philosophy; consciously he was molded by the English liberalism of his time; and less prominently he was affected by the Kantian epistemology, with its limitation of human knowledge to the phenomenal world. The Kantian influence was indirect, occurring through Spencer's reading of Hamilton and of Mansel. Spencer's popular influence has been very large—still larger in America than in England. His most notable undertaking is the effort to formulate the doctrine of evolution in general terms; as a part of the undertaking, his work in psychology, in sociology and, to a less degree, in educational theory and in ethics, has proved widely influential. H., 'Epitome of the Synthetic Philosophy' (New York 1901); Royce, J., 'Herbert Spencer: an Estimate and Review' (New York 1904 containing also personal reminiscences by James Collier).

JOSIAH ROYCE,
Late Professor of Philosophy, Harvard University.

SPENCER, Jesse Ames, Protestant Episcopal clergyman, author and educator: b. Hyde Park, N. Y., 17 June 1816; d. Passaic, N. J., 2 Sept. 1898. Having graduated from Columbia University and completed in 1840 a course in theology at the General Theological Seminary, he entered the ministry, becoming rector of Saint James Church, Goshen, N. Y., where he remained for two years. Later, he became professor of Latin and Oriental languages at Burlington College, 1849-50; accepted the position of editor and secretary of the Episcopal Sunday School Union and Church Book Society, serving from 1851-57; for two years, 1863-65, was rector of Saint Paul's Church, Flatbush, L. I., and from 1869-79 was Greek professor in the College of the City of New York and professor emeritus, 1879-81. His most important books were 'History of the English Reformation' (1846); 'History of the United States' (1856-69); 'Sketch of the History of the Protestant Episcopal Church in the United States' (1878); 'Memorabilia: Recollections of Sixty Years, 1826-86' (1890), etc. He also edited six volumes of Arnold's series of Greek and Latin textbooks (1846-50), etc. In 1883 the House of Bishops appointed him custodian of the Standard Bible.

SPENCER, John Canfield, American lawyer, son of Ambrose Spencer (q.v.): b. Hudson, N. Y., 8 Jan. 1788; d. Albany, N. Y., 18 May 1855. He was graduated from Union College in 1806, was private secretary to Governor Tompkins in 1807-09 and in the latter year was admitted to the bar. In 1811 he became master in chancery, was appointed judge-advocate-general on the northern frontier in 1813 and assistant attorney-general of New York in 1815. He served in Congress in 1817-19, was a member of the State assembly in 1819-20, acting as speaker in the latter year, and in 1824-28 he was State senator. He was one of the commissioners to revise the statutes of the State of New York and was special attorney-general in the prosecution of the Masonic murder of William Morgan (q.v.). In 1839-41 he was Secretary of State and Super-

intendent of common schools and in the last-named year was appointed Secretary of War by President Tyler. He was transferred to the Treasury Department in 1843, but resigned in the following year because of his disapproval of the annexation of Texas. He thereupon resumed his law practice, was afterward a member of various State commissions, was actively instrumental in introducing an improved common school system, and the organization of the State asylum for idiots was due largely to his efforts. He edited, with preface and notes, Henry Reeve's translation of Tocqueville's 'Democracy in America' (2 vols., 1838), and was joint author of 'Revision of the Statutes of New York' (3 vols., 1846). Consult Proctor, 'Review of John C. Spencer's Legal and Political Career' (1886).

SPENCER, Joseph, American soldier: b. East Haddam, Conn., 1714; d. there, 13 Jan. 1789. He entered the Northern army in 1758, rose to the rank of colonel and in 1775, at the suggestion of Washington, was appointed brigadier-general by Congress. He took umbrage at the promotion of Gen. Israel Putnam and was about to withdraw from the army but decided to remain and served around Boston until its evacuation. He was then transferred to the defense of New York, promoted major-general in 1776 and in 1778 he was placed in command in Rhode Island. He assembled his forces at Providence, and instituted a movement against the British at Newport which failed, resulting in his censure and retirement.

SPENCER, Joseph William Winthrop, American geologist: b. Dundas, Canada, 26 March 1851. After graduating from McGill University, Montreal, in 1874, where he took first honors in geology and mineralogy, he studied at the University of Göttingen, Germany, whence he was graduated Ph.D., in 1877. In 1877 he was appointed science master at the Collegiate Institute at Hamilton, Ontario; in 1880 became vice-president and professor of geology in King's College, Nova Scotia; in 1882 accepted the chair of geology in the University of Missouri, remaining there till 1887; and was State geologist of Georgia from 1888-93. He designed the museum building for the University of Missouri and procured many of the specimens for the geological department. In 1893, having come to New York, he became dissatisfied with the technical publications of the experimental stations and induced the legislature to appropriate \$8,000 for university extension of agriculture, the money being placed with Cornell University, part for carrying the Agricultural College to the farmer and part for the Experimental Station. In 1896 he was placed in charge of the department for a farmers' correspondence reading course and later, with the aid of the Department of Public Instruction, succeeded in introducing agriculture under the name of "nature study" into the public schools. In 1905-08 he was special commissioner of the Geological Survey of Canada. He has made extended investigations of glacial geology of the Great Lakes region and Niagara Falls and of the geologic history of the Antilles and Central America. His report on 'The Falls of Ni-

agara' (1907), in which the age of the falls is stated to be 39,000 years plus or minus 4,000 years, was issued by the Canadian Geological Survey. He has written 'Niagara, Fossils' (1884); 'Glacial Erosion in Norway' (1887); 'Geological Survey of Southwestern Georgia' (1891); 'Geological Survey of the Paleozoic Belt of Georgia' (1893); 'Origin of Niagara Falls and History of the Great Lakes' (1895); and many papers in scientific journals, relating to the same subjects.

SPENCER, Platt Roger, American penman: b. East Fishkill, N. Y., 7 Nov. 1800; d. Geneva, Ohio, 16 May 1864. At 15 he taught his first writing class; and from 1816-21 was employed as a bookkeeper. He then studied law and later became a teacher in the common schools. He was instrumental in the establishment of business colleges throughout the United States, and published 'Spencer and Rice's System of Business and Ladies' Penmanship'; 'Spencerian or Semi-Angular Penmanship.' What is known as Spencerian penmanship derives its name from him as its exponent.

SPENCER, Sara Andrews, American social reformer: b. Savona, Steuben County, N. Y., 21 Oct. 1837; d. 1909. She was graduated from the Saint Louis Normal School, 1856, and was married to H. C. Spencer in 1864. Having removed to Washington she with 72 other women attempted to register and vote in 1871 but was refused. She then brought suit which resulted in decisions of the Supreme Court of the District of Columbia and the Supreme Court of the United States that women could not vote without local enabling legislation. She was instrumental in the passage of a bill in the District of Columbia, 1873, for the rescue of outcast girls, and was secretary of the National Woman Suffrage Association 1874-81, and president of the Woman Franchise Association of the District of Columbia, 1871-76. She has published 'Problems of the Woman Question'; 'Thirty Lessons in the English Language.'

SPENCER, Sir Walter Baldwin, professor of history at the University of Melbourne: b. Stratford, England, 1860. He was graduated from Oxford and became professor of biology in the University of Melbourne in 1887 and director of the National Museum of Natural History, Geology and Ethnology. He was a member of the Horn Scientific Expedition to central Australia in 1894 and editor of its reports. With F. I. Gillen, he conducted an ethnological expedition across Australia to the Gulf of Carpentaria in 1902. He was knighted in 1904. He is joint author with Gillen of 'The Native Tribes of Central Australia'; and also of 'Northern Tribes of Central Australia'; and author of 'Pinal Eye in Lacertilia'; 'The Narrative of the Horn Expedition'; 'Across Australia' (1902); 'Native Tribes of the Northern Territories of Australia' (1914).

SPENCER, Iowa, city, county-seat of Clay County, on the Little Sioux River, and on the Chicago, Milwaukee and Saint Paul Railroad, 75 miles northwest of Fort Dodge and 80 miles northeast of Sioux City. It is in an agricultural and stock-raising region. Its chief industries are connected with farm and dairy products. It is a railway junction and local

commercial centre. It makes large shipments of corn, wheat, livestock, vegetables and dairy products. There are public elementary schools, a high school, a private commercial school, a library, banks and newspapers. Pop. about 3,005.

SPENCER, Mass., town, one of the county-seats of Worcester County, on the Boston and Albany Railroad, about 12 miles west of Worcester. It is in a beautiful region, about 1,000 feet above sea-level and surrounded by farm lands. It was settled in 1717 by Nathaniel Wood. Originally it was a part of Leicester, and in 1744 it was made the West Parish of Leicester, and in 1753 was incorporated as a town with the name of Spencer. In 1744 its first church was organized. It is the birthplace of Elias Howe (q.v.), inventor of the sewing machine. It has a large shoe factory, woolen mills, vinegar works and wire works. There are seven churches, the David Prouty high school, public and parish elementary schools, and the Richard Sugden Public Library, opened in 1857. There are several banks and newspapers. The government is administered by a board of five selectmen. Pop. about 6,740.

SPENCER GOLF, Australia, a large inlet of the Indian Ocean indenting the south coast of South Australia between Eyre and Yorke Peninsula. Sixty miles wide at the entrance, it widens to nearly 100 miles, and then narrows gradually into a fiord at Fort Augusta, nearly 200 miles inland.

SPENER, spä'nër, Philipp Jakob, German clergyman, "the father of Pietism": b. Rappoltswiller, upper Alsace, 13 Jan. 1635; d. Berlin, 5 Feb. 1705. Although called the founder of Pietism (q.v.), which resulted in a salutary reformation within the Lutheran State Church, none of the errors or extravagances which marked the development of the movement can be attributed to Spener. His early training revealed to him the necessity of a moral and religious reformation of the German Church and with a view to the ministry he studied practical Christianity at Strassburg, specialized in philology, history and philosophy, gained his degree of master in 1653, spent a year in Geneva where he was powerfully influenced by Leger and Labadie, studied also at Basel, Tübingen and Lyons, and in 1666 became a pastor at Frankfort-on-the-Main. Pietism developed from meetings at his house at which his sermons were discussed and the Scriptures were expounded. In 1675 he published his 'Pia Desideria, oder herzliches Verlangen nach gottgefälliger Besserung der wahren evangelischen Kirche' or 'Earnest Desires for a Reform of the True Evangelical Church.' It embodied proposals for the restoration of life in the church, chief of which were the serious study of the Scriptures in private meetings, *ecclesiola in ecclesia*, a smaller church within a church—a heart of spirituality; the universality of the Christian priesthood, the laity sharing in the spiritual government of the church; and regeneration or the promotion of personal piety instead of the inculcation of dogmatic beliefs. The work created a deep impression throughout Germany and much offense among orthodox clergymen, the more so that its premises were undeniable. The 'Pia Desideria' was followed in 1680 by 'Allgemeine Gottes-gelehrtheit.'

In 1686 he was appointed first court chaplain at Dresden, but soon offended his patron Elector John George III by his outspoken and uncompromising attitude in the fulfilment of his duties. His criticisms of the immorality of the wealthy classes had previously given offense, but in 1691 the court of Brandenburg was influenced to offer him a rectorship and he became 'Konsistorialrat' of Saint Nicholas in Berlin. In a court and government more inclined to rationalism than pietism Spener, however, was held in esteem and along lines advocated by him the university of Halle was founded in 1694 and became the centre whence pietism spread. He was a voluminous writer and the movement which he originated owing to the extremes to which some of his followers went was constantly attacked and abused by the orthodox. The theological faculty of Wittenberg in 1695 condemned as errors 264 propositions contained in his writings. Three years before his death he completed 'Theologische Bedenken' (4 vols., 1700-02). 'Letzte Theologische Bedenken' appeared posthumously with a biographical introduction by C. H. von Canstein (1711). Consult Gruneberg, P., 'P. J. Spener' (3 vols., Göttingen 1893-1906); Hossbach, W., 'Philipp Jakob Spener und seine Zeit' (Berlin 1828; 3d ed. 1861).

SPENLOVE-SPENLOVE, Frank, English painter: b. Sterling, Scotland, 1866. At the Paris Salon his 'Funérailles dans les Pays Bas' was awarded the gold medal of Paris and purchased for the Luxembourg (1901). He exhibited at the Royal Academy for the first time in 1886 and has been represented there every year since. Among his landscapes and genres may be mentioned 'After Summer Days'; 'Night's Awakening'; 'Gilded Pastures'; 'Over the Valley'; 'Avenues of Gold'; 'Picardy'; 'The Hurrying Storm'; 'A Winter's Tale—Funeral Blessings, Holland'; 'Unto This Last—The Pilot's Funeral'; 'Too Late'; 'Darsham Vale'; 'Autumn Glory'; 'The Little White Cross'; 'Grey of the Morn'; 'In the Shadow of the Church', etc.

SPENSER, Edmund, English poet: b. London (probably in East Smithfield near the Tower), about 1552; d. Westminster, 16 Jan. 1599. He was the eldest son of Elizabeth (cf. 'Amoretti,' LXXIV) and (perhaps) John Spenser, "free journeyman" in the "arte or mysterie of clothmakyng," in 1566 with one Nicholas Peele, "sheerman" in Bow Lane. A "John Spenser, son of John Spenser, gent.," known to have followed the poet through the same school and college, may have been a younger brother. In the Burnley district of N. E. Lancashire there was a family of Spensers, among whom the names John, Edmund, Lawrence were common. The poet had a son Lawrence. Edmund also shared in the benefactions of Dean Nowell, relative by marriage of the Lancashire Spensers.

This commonplace upcountry stock hardly invited celebration from the ambitious Court poet; but the Spencers of Althorpe, Northamptonshire, were a kinsfolk to be claimed and proclaimed. And, after 1590 at least, three daughters of Sir John Spenser, head of that "house of auncient fame," acknowledged and patronized their now famous, if still impecunious connection; he in return is profuse with dedication

and complimentary allusion. To one, Elizabeth, Lady Carey, he writes, dedicating 'Muiopotmos': ". . . I have determined to give myself wholly to you, as quite abandoned from myself, and absolutely vowed to your services." No doubt solely on the strength of this "platonic" vow, Nashe two years later (1593) assured Lady Carey in his dedication of 'Christ's Tears over Jerusalem' that 'Fame's eldest favorite, Maister Spenser, in all his writings he prizeth you.'

To his father's association with the Merchant Taylors' Company, and to Dean Nowell's help, Spenser apparently owed an excellent education. The recently (1561) founded Merchant Taylors' School offered free tuition to 100 poor boys and the "free journeyman's" son was doubtless one of these. Later, at Pembroke College, Cambridge, he matriculated 20 May 1569 as a "sizar," or student who for certain services was exempted from fees and given board and clothing. Moreover, Dean Nowell's accounts (ed. Grosart, 1877) show several gifts of money from 1569 on; and already in 1569 Spenser was earning money himself. At least, certain sonnets included by Ponsonby in the 'Complaints' of 1591 are manifest revisions from a certain 'Theatre for Worldlings' of 1569. This was an English translation of a Protestant polemical miscellany by a Flemish refugee physician, John Vander Noodt, resident at Christ Church school, and very likely known to Mulcaster, master of Merchant Taylors' School. Mulcaster's boys were especially trained in Italian and French and young Spenser may well have been recommended to Vander Noodt for the place. Moreover, Spenser was almost certainly behind Ponsonby in the publication of the 'Complaints'; and abundant internal evidence makes for the authenticity of the translated sonnets. These are from the 'Songe' added to DuBellay's 'Antiquitez du Rome,' and Marot's version in sonnets of Petrarch's *canzone* "Standomi un giorno, solo, alla fenestra." They illustrate interestingly the early maturing of the poet's elegiac Puritanism, stately archaic diction, and flexible verse. Though rhymed for the 'Complaints,' the Bellay "sonnets" of 1569 are in a blank verse better modulated than any other between Surrey and Marlowe.

Spenser took his B.A. at Cambridge 1573; M.A. 1576. Allowances for protracted illnesses indicate delicate health; but he was clearly an eager, if discursive, student. Following Mulcaster's lead, he read widely Italian and French literature as well as classic, the older English authors—especially Chaucer and Langland, moral and natural philosophy—especially the hybrid Platonism of the period. Harvey's nicknames for him—"Italianate Seignor," "Your French Monsieurship," etc.—recognize his cosmopolitan tastes. Training and temperament made him sharply partisan for the Puritans, whose leader in the University, Cartwright, was driven from his chair of divinity in 1570.

The young master of arts probably did not seek a fellowship. Had he failed, his friend Harvey was not the man to have kept silence. More poet than scholar, Spenser doubtless, like other needy Elizabethan poets, looked to place and patron and became first, it would seem, tutor or secretary in the family of a lady of

rank in the "North partes" of England; and was then, upwards of a year later, called by Harvey to Kent "for his more preferment."

This "Gentlewoman of no meane house" in the "North partes" is the "Rosalinde" of the 'Shepheards Calendar'; and the poet's pretense of blighted passion implies probably no more than regulation "loving" gratitude to lady-patron. He was, as she put it, "her Seignor Pegaso." Twelve years later, in 'Colin Clouts Come Home Againe,' he defends her against the charge of disloyal cruelty by pretty clear intimation that his "passion" had been but "Platonic" tribute.

The editor of the 'Calendar' says that the name "Rosalinde" "being wel ordered, wil bewray the very name of hys love and mistress"; and the hint may have enlightened a select few. But the possible anagrams—if anagram is meant—of "Rosalinde" are many; and the "feigned name" seems too good to be a strict anagram. Solutions have been numerous, but unconvincing. That she was a Lancashire "lasse" met by the young graduate on a visit to his relatives there, seems unlikely: an ambitious youth would hardly seek preferment among small farmers in a remote rural corner of England. The asserted Lancashire setting and dialect of the 'Shepheards Calendar' are uncritical myths: setting and language are not local, but literary and composite, artificial rustic ("Doric") and conventional "Arcadian." Moreover, there is Aubrey's statement, on the asserted authority of John Dryden, that "Rosalinde" was a "kinswoman" of Sir Erasmus Dryden's wife, who was a daughter of William Wilkes of Hodnell, Warwickshire, a place not far from the Cotswold Hills. Whatever difficulties may lie in calling these hills "North partes" at least Drayton, in one of his eclogues, set "Rosalinde" there.

From these "North partes" Spenser was called to become "the Southerne shepheardes boye" in Kent. Through the "shepheard," acceptedly Sir Philip Sidney, he may presently have been made secretary to Sir Henry Sidney, Lord-Deputy in Ireland. At least, in the 'Veue of the Present State of Ireland' (Globe ed., p. 636), Irenæus, Spenser's general mouthpiece, professes to have witnessed the execution of "Murrough O-Brein," 1 July 1577.

Two years later, 5 Oct. 1579, Spenser appears in the service of Sir Henry's brother-in-law, Leicester, and writing to Harvey from Leicester House. This letter and another, with Harvey's answers, were published, presumably by Harvey, a year later. They reveal 1579-80 as the poet's *annus mirabilis*. Brimful of publishing projects, eager for literary reforms, received at Court, had "in some use of familiarity" by such high society as Sidney and Dyer and by pretty women (to sober Harvey's alarm),—before the year-end he had achieved the program of a new poetic school, written its manifesto and outlined his own chief works to come. Among other projects, he informs his somewhat sceptical friend of a great Continental trip on Leicester's business. Then suddenly, as it seems, all this stops. He arrives in Dublin, 12 Aug. 1580, secretary to the new Lord-Deputy, Lord Grey de Wilton.

Meanwhile, but one of his several finished poems had been printed; and this under a

pseudonym and ostensibly on a friend's responsibility. The 'Shepherds Calendar,' finished before 10 April 1579—date of the editor's epistle to Harvey,—but not "entered" until December 5, appeared soon afterward, embedded in a literary apparatus full of mystifications. Secrecy, however open, was in the "amoris" code. More importantly, the "theological" eclogues expressed opinions close to treasonable and preferred unpleasant personal charges. The editor, "E. K.," played his part well, being at times clairvoyant of the author's secret meanings, at other times obtuse as "Ignaro" himself. He was doubtless Edward Kirke, once with Spenser at Pembroke College; but much of the "glosse" must have been inspired, if not dictated, by Spenser himself, who, if perhaps "furze estraunged" in April, was certainly in London in October 1579.

The 'Shepherds Calendar'—perhaps so-called from a popular almanac, the 'Kalender of Shepherdes'—contains, as its sub-title indicates, "twelve aeglogues proportionable to the twelve monethes." It was dedicated to Sir Philip Sidney. The "aeglogues" are of the Renaissance courtly type, in no proper sense poems of country life. The nature described is "Arcadian"; the description decorative; the real appeal personal and polemical. Tribute to a past patron, "Rosalinde,"—to a present patron, Leicester, in the dirge for his kinswoman, "Dido,"—to a hoped-for patron, the Queen, in the "laye of Elisa"; partisan support of Leicester's Puritanism against Burghley's "Anglicanism"; proclamation of his own Platonist poetics—such are the live interests; the rest, as E. K. says, is "recreative," little neo-classic idyls in porcelain. Such "pastoralism" is a poetry, not of nature, but of art,—goldsmith's art for nicety and "curious felicity" of detail. The 'Calendar' is the first English poem which rivals the poetic virtuosity of Renaissance Italy and France.

But "Immerito" justifies his editor's title of the "new Poet" in a larger sense. He appears in the 'Calendar,' like his master Du Bellay in the 'Deffence et Illustration de la Langue Francoyse,' as the spokesman of a school of "new poets"—Sidney, Dyer, Fulke Greville and perhaps others—who form an "Areopagus," in emulation of the "Pleiade," to promulgate in England the tenets of Du Bellay's and Ronsard's poetic reform. The poet is to be "defended" as an inspired teacher, born not made, but needing "laboure and learning" fitly to understand and to express his high message. By him the common speech must be "ennobled" (*illustrée*) by art into a really "poetic diction,"—inversely to Wordsworth's contention. The new poet's method is to be "assimilative imitation" of the classics primarily, but with a judicious eye to the best among modern and national models. Spenser's own pronouncement, 'The English Poete,' was not printed; Sidney may have worked it into his own 'Defense of Poesie,' the Platonist doctrine of which concurs with Spenser's. The question of "classical" metres was discussed by the "Areopagus," as it had been by the "Pleiade"; but the Harvey-Spenser correspondence has exaggerated its importance for the English school.

Spenser aspired early to be the English "Virgil"—the "*poeta novus*" of his own day—and in 1579 had already begun the epic designed

to follow his "low-flying" pastoral as the 'Æneid' followed the 'Bucolica.' Such indeed was, as E. K. says, the common aspiration of Renaissance poets. Du Bellay eloquently demanded for France a "*long poëme*" worthy to stand with the 'Æneid' and the 'Orlando Furioso.' For the Renaissance, however, Virgil was more than the poetic historian of the founding of Rome—the "*romanus Vergilius*" of Petronius; he was also the moral allegorist of Macrobius and Petrarch, and the unwitting Christian prophet of Dante. Spenser's first idea was, apparently, to re-express these patriotic, moral and religious motifs in the style of the 'Orlando Furioso,'—thus satisfying the eclectic ideal of the new school. In 1579 he sent Harvey a draft of his resulting 'Faerie Queene.' But Harvey was unconvinced by this attempt to "overgo" Ariosto; and Spenser worked away in silence for 10 years. Of the 'Faerie Queene' of 1590 Harvey was loud in praise; and in fairness, we may presume a radical recasting.

Until Lord Grey's retirement, August 1582, Spenser was his secretary. By March 1581, he had also purchased from Ludowick Bryskett appointment, with right of deputy, as registrar or clerk of the Faculties of the Court of Chancery in Dublin. He began, too, a series of land-speculation,—first buying, to sell immediately Abbey Enniscorthy in County Wexford, and an abbey in New Ross. Next, January 1582, he leased for six years the Dublin residence of the attainted Lord Baltinglass, and secured a "custodian" of Newlands in Kildare, property of a relative of Baltinglass. On August 24 he leased for 60s. a year "the dissolved house of Friars Minor of the New Abbey, in the county of Kildare, with its possessions"; and resided there at least during 1583–84, when he served as a commissioner of musters for the county. In 1590 his lease of New Abbey was forfeited for non-payment of rent. The Dublin house he used for business convenience; the conversations described in Bryskett's 'Discourse of Civill Life' took place probably in the spring of 1584 or 1585; and Spenser came daily from neighboring Dublin to join in them. Finally, his name appears in the articles, June 1586, for the Munster "undertakers" or colonizers, as lessee of the castle and lands, 3,028 acres, of Kilcolman, in County Cork. Although the patent was not passed until 26 Oct. 1591, Spenser must have taken possession by 1588–89, since in that year he reported six English settlers on the estate and also received Raleigh as guest. Rent was fixed at £8 13s. 4d. per annum, to be doubled after Michaelmas, 1594; there is record of payment for 1592.

On removal to Kilcolman he resigned, 22 June 1588, the Dublin clerkship, to purchase, again from Bryskett, clerkship of the Government Council of Munster,—Bryskett, however, apparently reserving a share in the reversion of the office. Spenser, like his master, Chaucer, was a shrewd man of business; but his shrewdness had its nemesis. Local feeling ran high against the undertakers. On 12 Oct. 1589, Lord Roche of Fermoy, English-born but Irish by sympathies, charged Spenser with unlawful dispossession of certain lands "by colour of his office and by making of corrupt bargains with certain persons pretending falselie title." This began a series of petty persecutions by Roche,—

once by "boycott," making "proclamation" that "none of his people should have any trade or conference with Mr. Spenser or Mr. Piers, or any of their tenants, being English,"—another time, by "fineing" a tenant of his own "for that he received Mr. Spenser in his house as he came from the session at Limerick." Probably for protest against Roche, as well as on Raleigh's invitation, Spenser left for London between October 12, when Roche brought suit, and December 1, when the first three books of the *'Faerie Queene'* were "entered."

Since, 10 years before, Spenser had boasted of "overgoing" Ariosto, he had grown in knowledge and experience: Bryskett draws him less poet than philosopher. Even in 1579, no two literary temperaments could have been more antipathetic than the Platonizing Puritan of Cambridge and London and the Horatian cynic, witty Ferrarese. After 1580, the *'Orlando Furioso'* remained for Spenser a storehouse of plot and incident and character in silhouette (cf. R. E. N. Dodge, *Publ. Mod. Lang. Assoc. Amer.*, 1897); but for the essential things,—spirit, manner, ideals—Tasso's *'Gerusalemme Liberata'* became his intimate model. The later epic better fitted Du Bellay's ideal in its high seriousness—at once religious, moral, and patriotic,—in its form and manner sensitively refined, pictorial, and—as the Renaissance understood the word—classic. Temperamentally, Tasso and Spenser were sympathetic, even—difference of creed notwithstanding—in their sombre religiosity. Elizabeth in 1584 envied the Duke of Ferrara his laureate; Spenser was even then preparing to fill Tasso's rôle in England.

The *'Faerie Queene'* was designed to be an allegory, in 12 books of 12 cantos each, of the "ethike part of philosophy" which concerned private conduct; and a sequel was promised, allegorizing political or princely conduct. To add the national note, the hero was to be *Prince Arthur* embodying the private virtues, *King Arthur* the political. The central motive of this virtual "conduct-book" shows the influence of the most famous "conduct-book" of the age, Castiglione's *'The Courtier.'* Prince Arthur's mystic love for the dreamed-of Gloriana—the faith whence all his good works spring,—while it has roots in mediæval romance, is raised to a power for righteousness by the Neo-Platonism to which, as applied to womanly influence, Castiglione, following Bembo, gave international vogue.

Harmonization of Neo-Platonism with Catholic theology had been a commonplace since Ficino, not to say Origen; Spenser's idea was to harmonize Neo-Platonism with Puritan theology. His method can be seen in the *'Fowre Hymnes'*: the first pair, composed in the "greener times" of his youth, superbly voice a nearly pure Neo-Platonism of the type of Benivieni; the second pair, 1596, somewhat mechanically transpose the theme to the key of Tyndale and Calvin. Following his eclectic method, Spenser in the *'Faerie Queene'* incorporated other doctrinal items, notably Aristotle's doctrine of "moderation" and his moral categories, as already modified by Italian commentators into 12. The allegory of the Puritan's "battle between the Spirit and evil lusts"—error, hypocrisy, pride, despair,—the chief and principal work of faith, the battle of

the Spirit against the flesh" (the "Old Dragon"),—the comforting by divine Truth (Una) of his soul overcome by Despair,—the necessary mediation of divine Grace (Arthur)—all this is already adumbrated in Tyndale's *'Prologue upon the Epistle of Saint Paul to the Romans'* (republished in Works, 1573).

Spenser's problem was to express this eclectic system through a roman narrative itself constructed from many sources—Classic, Mediæval, Renaissance—the personages of which should represent its categories, and their ordered adventures its dialectic; and, at the same time, also to "shadow forth," as through a double veil, the religious, political and contemporary social history of England. No other European poet except Dante had essayed so prodigious a task; and Spenser may have been emulating Dante. But the English poet was infinitely less happy in his medium: the cloudily shifting scenes, monotonous ill-motivated exploits, vaguely or externally differentiated characters of popular chivalric fiction offered but a poor substitute for the Tuscan's accurately symbolic, yet localizable and tangible other world of nicely discriminated human realities.

The curiously protean poem, however, even in its weakness, was nicely calculated to contemporary taste. It had something for all,—high if vague doctrine for thinkers,—classical learning and Italianate elegance for scholar and dilettante,—romantic story, graphic picture, piquant gossip for courtier or fine lady; and the cultivated Elizabethan often united in himself all these moods. Spenser was at once acclaimed supreme poet of his generation. Exception may have been taken by some, as by Jonson, to the artificially archaic diction—attempt on Pleiadist principles, to dam up current speech at its Chaucerian "well of English undefyled," or to the complicated stanza itself probably also from Chaucer—the *'Monkes English poet'*, unless Chaucer, has been in his *Tale* stanza capped by an Alexandrine; but no lifetime so undissidently lauded.

In February 1591 an annual pension of £50 was allotted, a stipend—if paid!—worth several times that of the present Laureate. Spenser was probably disappointed, however, for another reason. On his own testimony (especially, *F. Q.* VI, xii, 41) and that of contemporaries, his writings had angered all-powerful Burghley. Puritan Leicester's partisan and protégé, Spenser had lost no opportunity to attack the policy, as well as by innuendo to insult the character of Leicester's lifelong opponent. No contemporary could have failed to find Burghley among the "bigge Bulles of Basan" of the "September" eclogue (I, 124), or in the arraignment of official "graft" of *'Mother Hubberds Tale'* (II, 515 ff.), or in the libel of "counsellor" Fox (*ib.* II, 1127 ff.), or in the jealously mean-spirited minister of the *'Ruines of Time'* (II, 447 ff.). From a hostile viewpoint, the cap fitted. Even loyal Harvey later (*'Fowre Letters,'* ed. Grosart, I, pp. 164–165), regretted that "Mother Hubberd, in heat of Choller, forgetting the pure sanguine of her sweete Faerie Queene, wilfully overshot her malcontented selfe." Apparently both *'Mother Hubberds Tale'* and *'The Ruins of Time'* were supposed or "cald in againe" (cf. Pref., *'Father Hubberds Tales,'* 1604; John Weever: *'Epigrams,'*

1599). Burghley, long-suffering with Leicester himself, may well have blocked preferment in England for Leicester's "man." Such seems to be the veiled grievance of 'Virgil's Gnat,' Spenser ("Gnat") for serving Leicester ("Shepherd") against Burghley ("Snake") is sent off to Ireland "waste wilderness. . . Cimmerian").

Spenser remained in England until after the beginning of 1591. 'Daphnaïda' was dedicated from "London, this first of January, 1591." The date is undoubtedly "New Style." The lady, Douglas Howard, whose death is lamented, died late in 1590; and the dedication of 'Colin Clouts Come Home Againe' to Raleigh "From my house at Kilcolman, the 27 of December 1591" circumstantially proves Spenser's return. Assumption of a dramatic fiction in the latter dedication (cf. P. W. Long, N. Y. *Nation*, 1 Nov. 1906) is uncalled for: use of "New Style" dating is by no means uncommon among literary Elizabethans; Gascoigne as early as 1575 appears to have used it side by side with "Old Style" (cf. J. W. Cunliffe: 'Supposes and Jocasta,' Boston, 1906, p. vi, n. 1); Jonson used it mainly; in the 'Shepheardests Calendar' and in 'Amoretti' IV, Spenser starts the "new year" with January. The 'Daphnaïda,' perhaps built on the lines of Chaucer's 'Boke of the Duchesse,' is itself a "funeral complaint" set in a "vision," and in the falsetto key of hired mourning; its representation of the hapless lady by an heraldic pet lion is a monumental piece of bathos.

A collection, entitled 'Complaints,' 'entered' 26 Dec. 1590, appeared 1591. The poems were mostly earlier ones, revised, and were possibly published before. Of the 'Ruines of Rome' and 'Mother Hubberds Tale' there is a manuscript extant decidedly varying from Ponsonby's text (Brit. Mus. Add. MS. 34064; cf. 'Modern Language Notes,' XXII, No. 2). Ponsonby's foreword, accepting responsibility for the volume, and referring to Spenser's "departure over sea," would naturally indicate that the collection was "made up" in the author's absence. But Spenser was certainly in England when the book was "entered"; and Ponsonby would hardly have "pirated" from his best client. Doubtless Ponsonby's foreword, like E. K.'s "glosse," was a "blind" to avert possible consequences from such plain speaking as the 'Complaints' contained.

The common motif of these is that of mediæval "tragedy," — the ever-turning of Fortune's wheel and the upsetting of great expectations. The theme, modified by the antique notion of "Fate," still dominated the Renaissance imagination, inspiring in England the huge 'Mirror for Magistrates,' the "chronicle-history" plays, and much more, including Vander Noodt's 'Theatre' itself. Too much may, therefore, be inferred as to Spenser's own temperament from such fashionably melancholy meditations. There is indeed strong personal feeling in them, certainly grief for Sidney and animosity against Burghley, but much is conventional literary exercise. The 'Ruins of Time' follows in scheme the 'Ruins of Rome,' translated from Du Bellay; the 'Visions of the Worlds Vanitie' echo the 'Visions' from Du Bellay and Petrarch; 'Muiopotmos' is an airier variation on 'Virgil's Gnat,' translation of the pseudo-Virgilian 'Culex'; the idea of the 'Teares of the Muses' had already been

developed in Ronsard's 'Dialogue entre les Muses deslogées et Ronsard' and in Harvey's more personal 'Musarum Lachrymæ'; 'Mother Hubberds Tale' is an adaptation of 'Reynart the Foxe' with Renaissance accretions (cf. E. A. Greenlaw, 'Mod. Philol.,' Chicago, Jan. 1905).

'Colin Clouts Come Home Againe,' although its dedication is from Ireland, may have been written and disseminated in manuscript while Spenser was still in London. The eclogue is a kind of poetic "P. P. C." to the poet's English hosts, — Colin telling his rustic companions about Kilcolman, of the lights — and shadows — of the Court over sea. But 'Hobbinol' (usually Harvey) was certainly in England. The whole piece is a model of subtly modulated compliment, scaling up to the platonic homage to Spenser's royal mistress, then resolving into the minor of the apology for his "rustic" mistress. The eclogue was printed with 'Astrophel,' 1595.

Shortly after Spenser's return to Kilcolman, he fell in love; and after more than a year of courtship, married 11 June 1594, Elizabeth Boyle, "cozen" of Richard Boyle, later 1st Earl of Cork. "Elizabeth's" identity is established from Boyle's memoirs ('Linsmore Papers,' ed. Grosart, 1868-88, in which she appears as mother of Peregrine Spenser and wife of Roger Seckerstone, whom she had married in 1603. In 1613, again a widow, she married Captain, later Sir Robert Tynt. The kindlier tone toward Ireland of Spenser's later poetry indicates domestic happiness.

On 19 Nov. 1594, five months after Spenser's wedding, Ponsonby "entered" the 'Amoretti' and Epithalamion written not long since by Edmund Spenser, and issued the volume, 1595, ostensibly on his own initiative; but his vague foreword implies that he had received the manuscript from the author himself. The titular coupling of the two pieces must have suggested their dramatic connection, four little neo-classic idyls serving as a "recreative" *entracte*. Both describe in identical terms one heroine, stately to haughtiness, rosy-cheeked, golden-haired, blue-eyed. After the traditional sonnet-cycle formula — "the prologue, hope; the epilogue, despair" — the 'Amoretti' close with a lovers' quarrel, allusion to which may lie in "the paynes and sorrowes past" of the 'Epithalamion' (i. 32). Phrase and conceit are imitative; but — one may go awooing with conventional manners in a borrowed coat. In form, the schema of "linked" quatrains compromises between the close-knit Italian sonnet and the loose Shakespearian. The gorgeous 'Epithalamion,' redeemed from mere goldsmith's work by its exuberant feeling, follows not unworthily the Italian *canzone*. To these two "goodly ornaments" for his bride, Spenser added a charming pendant in the idyl of Colin piping to his "country lasse," a fourth Grace in the midst of Venus' damsels (F. Q. VI, x).

The "poet-undertaker" had been having other troubles besides the doubts and delays of his long courtship. He was again sued by Roche, and was dispossessed, by default of appearance, 12 Feb. 1595 (N. S.), of three "plough lands, parcell of Ballingrothe." To conduct his case he assigned his clerkship of the Munster council to one Nicholas Curteys, who thereafter, "upon the trust of Lodowick Brys-

kett and Edmund Spenser," retained the "poor and troublesome place" until superseded by Richard Boyle, February 1598.

The second three books of the 'Faerie Queene' were finished by 1594 ('Amoretti,' LXXX). Spenser must have carried the manuscript to Ponsonby between February 1595, when he appeared against Roche, and 20 Jan. 1596, when the poem was "entered." He dedicates his 'Fowre Hymnes' from the Court at Greenwich, 1 Sept. 1596. On November 8 he attended—as his 'Prothalamion' for it implies—the double wedding at Essex House between the Earl of Worcester's daughters, Elizabeth and Catherine Somerset, and Essex's friends, Henry Guildford and William Petre.

Now that his old patrons—Sidney, Leicester, Grey—were all dead, Spenser was courting Sidney's widow's husband, Essex, of whom the 'Prothalamion' is principally a panegyric. Meanwhile, the 'Astrophel,' an elegy for Sidney—with companion-pieces by other hands,—had appeared with 'Colin Clouts Come Home Againe,' 1595. One piece, Bryskett's 'Mourning Muse of Thestylis,' had been separately "entered" 22 Aug. 1587; and possibly, the whole series was resurrected for sake of the dedication to Lady Essex. Her acceptance of a poem celebrating Sidney's "amour" with Lady Rich further testifies to the purely "platonic" nature of that "amour."

These publications of 1595-96 emphasize the poet's growing worldliness. Sharp-tongued radical moralist gives place to polished and discreet court laureate—by assumption if not appointment. Nobility for him is rather of caste than of character: "court and royal citadell" are the great school-maistresse of all courtesy" (F. Q. III, vi, 1). Most of his work is "occasional," even in the later books of the 'Faerie Queene' itself, his mirror is held up less to universal humanity than to the Court; historical and personal allusions multiply, relatively crowding out the moral allegory. Book V is part *apologia* for Lord Grey, who had died in 1593, part chronicle—often *chronique scandaleuse*—of national and social affairs "writ to the meridian" of Hampton and Greenwich. The libel on Mary of Scots as "Duessa" brought from King James, 12 Nov. 1596, a demand for legal redress. As art, however, the best of this later work realizes to the full the Italianate Renaissance ideal of sensuous grace (*leggiadria*),—brilliant dissolving views drawn in "an easie running verse with tender feet."

More touched with abstract thought are the two cantos and a fragment, perhaps part of a book on 'Constancy,' and first printed in the folio works, 1609. Influenced by Burno's 'La Bestia Trionfante,' "Nature's" overthrow of "Mutability" has a touch of pantheism not quite in harmony with the rest of Spenser's frankly patchwork system. The underlying intention may be a side thrust at governmental "mutability" in Irish policy, parallel to the indictment in the 'Veue of the Present State of Ireland.' This was first printed by Sir James Ware in 1633, but endorsed by Spenser (*finys* 1596,) and "entered" by Mathew Lownes, 13 April 1598. By implication of the opening sentence, it was written in England. In the dialogue, Eudoxus, the "wisely docile," is convinced by Irenæus, the "peace-lover," that distraught Ireland needs

"violent medecynes"—Machiavelli's "*medicine forti*." The treatise was disseminated in manuscript copies, of which several are extant. Later, early in December 1598, Spenser, a fugitive at Cork, used Tyrone's disastrous uprising as an object-lesson for the Queen of his 'Veue,' in 'A Briefe Note of Ireland,' with "Certaine points to be considered of in the recovery of the Realme of Ireland." In 1657, "Iron" Cromwell found in Spenser's sympathetic 'Veue' reason for maintaining Spenser's grandson in possession of Kilcolman.

On 30 Sept. 1598, Spenser was made sheriff of Cork. Less than a month later, Tyrone's rebels burned his house over his head; he and his family fled for their lives to Cork. Whether or no was added the horror of "a little child new born" perishing in the flames, as Jonson told Drummond, the shock and later privations undoubtedly broke the poet's frail constitution. He sailed, December 9, with despatches from Sir Thomas Norreys, president of Munster, to the Privy Council; delivered these December 24; on Saturday, 16 Jan. 1599, died at Westminster,—according to Jonson, "for lacke of bread in King Street," having declined Essex's aid. Jonson may have exaggerated; but contemporaries agree that the circumstances of his death were tragic.

He was given a sumptuous funeral—at Essex's expense, Camden says; and Browne, in 'Britannia's Pastorals,' declares that money given by Elizabeth for a monument was misappropriated. The present monument, restored in 1778, was erected by Anne, Countess of Dorset, in 1620.

The commingling of classic and romantic elements in Spenser's poetry has led—as with the Pleiade—to a curiously fluctuating appreciation. To his own age another "Virgil," Spenser seemed to the "Augustan" age a barbarous "Goth," to the Romanticists a genius full of glamor and witchery, to later Realists a brilliant, but uneven, word-painter. Each appreciation was justified from its own viewpoint. Milton valued the "teacher"; D'Avenant and Dr. Jonson patronized the evoker of pretty, but distempered, visions. The Jacobians—the three Fletchers, Browne, More, Joseph Beaumont, Bunyan, Cowley—read and imitated Spenser as Jonson recommended, mostly "for his matter," writing didactic allegories in heroic or pastoral vein. Milton and Dryden acknowledged him their spiritual master. Prior opened a long series of external imitation in form—verse and archaism. With Thomson's 'Castle of Indolence' and 'Seasons' begins a richer discipleship, which—sobered by the joint influence of Milton—has lasted to the present day, but culminated in the contemporaries of Wordsworth and Keats. Spenser has amply earned the title of "poet's poet," for his own exquisite art, and for the art begot in others: he has been the "Warwick" of English poets, the poet-maker. His manner has not invited translation: the few German and Italian versions from the 'Faerie Queene' are unimportant. For so great a poet his influence has remained singularly national. See FAIRY QUEEN, THE; SHEPHERD'S CALENDAR, THE.

Bibliography.—The fullest life of Spenser is by A. B. Grosart (Vol. I, 'Complete Works,' 10 vols. but 9 issued, 1882 ff.). Grosart un-

earthed much new information; but his enthusiasm often runs away with his judgment. J. W. Hales (Globe ed., Spenser 1897), and Dictionary of National Biography summarizes as established fact most of Grosart's inferences. The most suggestive studies of Spenser's personality as man and poet are by Lowell (1875), R. W. Church, 'English Men of Letters' (1879), and J. J. Jusserand 'A Literary History of the English People' (Vol. II, 1906). A composite photograph of the three portraits, each of which is from a different viewpoint, is not unlikely to be near the truth.

A critical edition of Spenser's Works remains a desideratum. The Globe text is as good as any. H. J. Todd's variorum edition (1805) is the basis for most following annotations through J. P. Collier's (1859). The 'Faerie Queene' has been separately annotated by Ralph Church (1758), Burves (1872), K. M. Warren (1897), and others; Books I, II for school use, by G. W. Kitchin (1868); Book I more elaborately, by H. M. Percivall (1894); 'The Shepherds Calendar,' excellently, by C. H. Herford (1895). The first edition of the 'Calendar' has been reproduced in facsimile by H. O. Sommer (1890). An 'Outline Guide to the Study of Spenser,' by F. I. Carpenter (Chicago 1894), will be found useful.

J. B. FLETCHER,

Professor of Comparative Literature in Columbia University.

SPENSERIAN STANZA. See SPENSER, EDMUND.

SPERM-WHALE. See WHALE.

SPERMACETI. See WHALE.

SPERMATOPHYTES. See BOTANY; FUNGI.

SPERMATOZOON, the male element; one of the flagellated cells developed in the testes (see TESTICLE) of male animals, and conveyed in their secretion (sperm or semen) to an egg of a female of the same kind, by copulation, or otherwise, for the sake of coalescing with (impregnating or fertilizing) that egg, and setting up the developmental changes which result in the formation of a new living being. The spermatozoa are extremely minute bodies, nearly always motile, usually slender and whiplike, tapering toward one extremity, and commonly with a rounded head at the other; and are developed by a succession of cell-divisions from certain cells in the testicle, called the primitive male cells, similar in character to the immature ova. It appears an individualized living cell, swimming about in the semen. The manner in which the spermatozoon unites with the ovum is explained in the article EMBRYOLOGY. It was the belief of a school of naturalists of the 17th century, called "Spermatists," that the whole of the resulting being was enfolded in and derived from the spermatozoon; while an opposing school the "Ovulists" asserted that in the egg alone was contained the germ of the animal. (See PREFORMATION). Neither was right; the development of a fetus results from a union of both male and female elements. See CELL; EMBRYOLOGY; and consult authorities mentioned thereunder.

SPERMOPHILE, a ground squirrel of the genus *Spermophilus*, of which more than 20 species exist in the United States while

several occur in Europe and Asia. They are rodents of a squirrel-like form. They live in underground burrows, bring forth their young in the burrows, are prolific, and in northern districts they hibernate in the fashion of marmots. They occur in the United States westward from Illinois, and into Mexico and Canada. When they become numerous in cultivated sections they are a troublesome pest, owing to their burrowing habits, although their burrows are not so extensive as those of the prairie dogs. They are commonly, but erroneously, called gophers in western districts; while in Europe they are known as suslik. The flesh is edible.

SPERRY, Charles Stillman, American rear-admiral: b. Brooklyn, N. Y., 3 Sept. 1847; d. Washington, D. C., 1 Feb. 1911. He was graduated at the United States Naval Academy in 1866, and was promoted through the various grades to commander 22 June 1896, captain 1 July 1900 and rear-admiral 26 March 1906. He was on ordnance duty at the Brooklyn Navy Yard during the Spanish-American War; was commander of the *Yorktown*, stationed at Manila in 1899; and in 1903 was appointed president of the Naval War College at Newport and a member of the General Board. He commanded the Second Squadron of the United States battleship fleet in the first lap of its cruise around the world in 1908-09 and was its commander-in-chief on its departure from San Francisco, 7 July 1908, succeeding Rear-Admiral Evans. He was retired 3 Sept. 1909.

SPERRY, Elmer Ambrose, American electric engineer: b. Cortland, N. Y., 12 Oct. 1860. He studied at the Cortland Normal School in 1876-79 and at Cornell University in 1879-80. He founded the Sperry Electric Company in Chicago in 1880, engaging in the manufacture of arc lamps, dynamos and other electrical appliances. He perfected one of the first arc lamps, and invented the gyrocompass, aeroplane and ship stabilizers, the highest intensity searchlight (1,500,000,000 candle power), gas engines, fire control apparatus and many special devices for the United States navy. Since 1910 he has been president of the Sperry Gyroscope Company, Brooklyn, N. Y., engaged in manufacturing his own inventions. He has received many prizes and awards for his inventions, both at home and abroad. Since 1915 he has been a member of the Navy Consulting Board.

SPERRYLITE, an important ore of platinum, consisting of the arsenide Pt As₂, containing 56.5 per cent of the metal. Occurs at mines in Albany County, Wyoming.

SPESSARTITE, a gem variety of garnet obtained from mines at Amelia, Va.

SPEUSIPPUS, spū-sīp'ūs, Greek philosopher: b. about 394 B.C.; d. Athens, 336 B.C. After the death of his uncle Plato, he became head of the Platonic school or Older Academy. Of his philosophical works, in which he taught a doctrine differing but little from Plato's, nothing is left but titles and fragments. He held that nature was not wholly good since wickedness is an essential factor in the progress of humanity.

SPEYER, James, American banker: b. New York, 22 July 1861. He was educated at Frankfort, Germany, and entered his family's banking-house in that city in 1883. He was

subsequently connected with the Paris and London branches of the firm before returning to New York. He became the head of the family firm of bankers and was an officer in many other banks and trust companies. He was one of the founders of the Provident Loan Company and a trustee of Teachers' College, Columbia University, to which he in 1902 presented the Speyer School. He was actively connected with the defeat of the Tammany Hall organization in 1894.

SPEYER, or SPEIER. See SPIRES.

SPEYERS, Arthur Bayard, American naval officer: b. New York, 15 Aug. 1846; d. Montreal, province of Quebec, 19 Nov. 1918. He was admitted to the United States Naval Academy in 1863, where he remained until six months before the close of the Civil War in 1865, when he was assigned with other members of his class to duty as acting midshipman on vessels assigned to destroy privateers. At the close of the war he returned to the Naval Academy, where he was graduated in 1868. His first assignment was to the North Atlantic fleet. A year later he was promoted to the rank of ensign and transferred to the *Benicia* on the Asiatic station. Two years later he was promoted to master, and while serving on the *Kansas* in 1874 was commissioned lieutenant. He was made lieutenant-commander in 1895. Soon after the beginning of the Spanish-American War in 1898 he was assigned to command the *Cæsar* and took part in bottling up Cervera's fleet in the harbor of Santiago de Cuba. At the close of the war, Commander Speyers was placed in command of the *Glacier*. He retired with the rank of rear-admiral, 11 Jan. 1905.

SPEZIA, Italy, city in the province of Genoa, on the Bay of Spezia, 56 miles by rail south of Genoa. It is built near the site of the ancient Roman *Lunum* and became the chief naval station of Italy in 1861, since which time its size has greatly increased. The harbor is the largest and best in Italy, and its entrance is protected by forts and by submarine embankments two miles long. It has large shipbuilding works, docks and a marine arsenal, as well as barracks and a hospital. The gulf and the surrounding country are especially beautiful, and the town has a considerable business as a winter resort, and is popular for bathing in the summer. There are exports of oil, pig lead, silver, wine, fruit, flour, marble and sandstone. Pop. (commune) 73,599.

SPHACTERIA, sfāk-tē'ri-ā (the ancient SPHAGIA), Greece, a narrow island, about two and one-half miles long, lying across the entrance to the Bay of Pylos on the southwestern coast of Messina. It is noted for two famous naval battles which took place off its shores, one in ancient and one in modern times. See PELOPONNESIAN WAR; NAVARINO.

SPHAGNUM, a genus of mosses, the only one of the family *Sphagnaceæ*, growing in moist places or bogs, in such quantities as to form a soft, thick carpet, saturated with water, whence their common name of bog-mosses. They are perennials of feathery aspect, growing at the top of the stem from year to year. Some of the numerous lateral branches grow upward, and form tufts at the apices of the stems, while others droop downward and envelope the lower

portion of the stem. Each year one of the side branches grows so strongly as to rival the main head, and thus gives a forked appearance to the plant. The lower end of the stem is continually dying away, eventually forming peat, and thus frees the lower ends of the branches, which thereupon start into independent plants. Special branches, differentiated by structure and color, produce the sexual organs, the two sexes being either on the same plant or separated. The spore-capsules are on short branches and are globular, with a lid. The leaves are small, translucent, and, like the stem, have strata of transparent cells, connected by holes, which are capable of absorbing and retaining much water. This ability to retain water has made the sphagnum moss very valuable to florists, who use it for packing bulbs and flowers, and it forms a large part of the compost employed for growing pitcher-plants and orchids.

SPHALERITE, the commonest ore of zinc. See BLENDE.

SPHENE. See TITANITE.

SPHERE, a ball or globe, defined in geometry as a solid bounded by a surface which is everywhere equally distant from a central point. If an arc equal to a semi-circle be made to rotate about the straight line joining its extremities, it will generate in space a spherical surface. Any section of a sphere by a plane will be a circle; when the plane passes through the centre of the circle of the section is a great circle; any other section is a small circle. A straight line passing through the centre and terminating at the surface is a diameter; a straight line from the centre to the surface is a radius. The surfaces of spheres vary as the squares of their radii. If a spherical surface be cut into rings by a set of parallel planes, the surface of each ring is a zone, and the area of any ring is proportional to the distance between the two planes which determine it, and the area of the ring is to the total area of the spherical surface as the distance between the two planes is to the length of the diameter. The mathematical relationship of things is apparent from the discovery by Archimedes (q.v.) that the surface of a sphere is equal to the curved surface of a circumscribed cylinder, while the volume is precisely two-thirds that of the cylinder. See TRIGONOMETRY.

SPHERICAL HARMONICS. See HARMONIC ANALYSES.

SPHEROGRAPH, a disc upon which is placed the earth in stereographic projection, the meridian and latitude lines being laid down completely, so that with a ruler and index a navigator may determine angular positions in great-circle sailing. It is also useful in a variety of problems in spherical geometry.

SPHEROIDAL STATE or **CONDITION,** the state of a liquid when it presents spherical phenomena caused by placing it on a very hot surface; the so-called "caloric paradox." Leidenfrost observed that a drop of water placed on a very hot surface assumed a spheroidal shape and did not touch the surface. Boutigny made a more thorough study of the subject, and experimented with various liquids. The limit of temperature of the hot surface is the temperature at which the drop of liquid spreads on it and boils with a hissing noise.

ANIK

CRIOSPHINX

ANDROSPHINX

CRIOSPHINX

Boutigny places the limit for water at 142° C., and at 61° C., for ether. The temperature of a drop of liquid in the spheroidal state is always below that at which the liquid boils, and for this reason the interesting experiment of freezing a small quantity of water on a hot platinum dish may be performed. The dish is heated almost to a white heat, when a small quantity of sulphurous acid is placed upon it, and assumes the spheroidal state; the boiling point of sulphurous acid is —10° C., and in the spheroidal state it is a temperature less than 10° C.; a few drops of water added to the sulphurous acid is immediately frozen, and may be thrown out of the dish, a mass of ice. Substituting nitrous oxide for sulphurous acid, and mercury for water, mercury may be solidified in the same manner.

That the liquid does not touch the surface is made evident in various ways, such as that of making the surface a flat plate and observing that light passes between the spheroid and the plate, or letting a conducting point enter the spheroid from above, and seeing if a current of voltaic electricity will pass between the spheroid and the dish. The temperature of the spheroid is kept low by the rapid evaporation which is going on at its surface; the spheroid is kept from touching the dish by a cushion of vapor, and this cushion is non-conducting, so that the heat which affects the spheroid is heat radiated from the dish; as soon as the temperature of the dish is less than that component to provide a cushion of vapor sufficiently dense to sustain the spheroid completely from contact with it, the spheroid spreads on the dish and is quickly dissipated by the heat which it now receives by contact. Consult Barker, 'Physics' (1893); Daniel, 'Text-book of the Principles of Physics' (3d ed., 1894); Stewart, 'Elementary Treatise on Heat' (6th ed., 1895).

SPHEROIDAL WEATHERING. See EXFOLIATION.

SPHINX, The, a mythological monster variously described but usually with a lion's body, the head and sometimes the breasts of a woman, the wings of a bird and a serpent's tail, supposed to represent some ancient symbolism. The Egyptians called the sphinx *Hu*, or *Neb* (Lord). Its present name is derived from the Greek *σφιγξ*, sphinx, "the binder," "strangler;" from *σφιγγειν* *sphingein*, to strangle.

The sphinx, like the obelisk (q.v.), in the mythology of the ancient Egyptians, represented the solar deity, *Ra*, and they were originally placed, like the obelisks, in pairs at the entrances of the temples and palaces, not for ornamental purposes only, but mainly for worship. It was emblematical of *Har-em-klu*, "Horus on the Horizon," the Harmachis of the Greeks, representing the conflict of lights and darkness, the conquest of Horus over Typhon, the slayer of his father, Osiris. The Pharaohs of the Middle Kingdom multiplied their number, and placed rows of them on both sides of the principal avenues leading to the temples and palaces of Thebes. The avenues of the temple at Karnac were bordered by hundreds of these sphinxes, many of which still remain, headless and disfigured. Those, however, were not only *andro* sphinxes, but of the *hieraco* and *crio*-sphinx type.

All nations of antiquity seem to have held

those monstrous beings of various shapes and forms as objects of awe, compelling adoration and worship. The ancient Egyptians believed that the sphinx also represented the Pharaoh who styled himself *Se Ra*, the son of *Ra*. Thus, on the pyramidion of the Obelisk of Thothmes III, in Central Park, there is a figure of that Pharaoh paying homage to a sphinx upon a pedestal, which in itself is a representation of the king. In other words, the king is worshipping himself.

The portals of the rising and setting sun were guarded by those lion deities. Even the Bible speaks of the Cherubim, which were placed to guard the entrance of the Garden of Eden. The real meaning of cherub, however, is still in dispute, but all agree that it was a composite winged being. The prophet Ezekiel describes similar beings in connection with the Divine Throne. The Assyrian conceptions of their guardian deities were chiefly represented by human-headed lions or bulls; eagle-headed human bodies, or vice versa.

The sphinxes of the ancient Egyptians were, as already mentioned, of three different forms, namely, (1) *Andro*-sphinx, a human-headed lion, symbolizing strength and intelligence; (2) *Crio*-sphinx, a ram-headed lion; (2) *Hieraco*-sphinx, a hawk-headed lion.

One of the most important relics of ancient Egypt is the colossal human-headed lion, in front of the second pyramid of Gizeh. Even in its present dilapidated state it elicits the wonder and admiration of the traveler. The Arabian traveler and historian Abdullatif (1162-1231 A.D.), in his description of the pyramids and sphinx, says: "At a little more than an arrow's flight from the pyramids is a colossal figure of a head and neck projecting from the earth; the name of the figure is '*Abu'l-hol*' " which means "Father of Terrors." The same authority speaks of it as having excited his attention more than all the other marvelous monuments put together that he had seen in Egypt. "Everything," he observes, "in spite of its enormous size, was in proportion to nature." "In a face of such colossal size" he wonders "how the sculptor could have been able to preserve the exact proportions of every part, seeing that nature presented him with no model of a similar colossus, or anything at all comparable." (DeSacy's trans., p. 180).

It is at a distance of about 1,800 feet from the Great Pyramid, and is carved from the solid rock upon which it rests. Its dimensions are (Smith's measurements):

	Feet	In.
Height of head from bottom of chin to forehead.....	19	
Horizontal diameter on level of forehead.....	23	
Circumference at level of forehead.....	72	
Horizontal diameter near broadest part of head-gear.....	29	
Circumference at broadest part of headgear.....	91	
Height of neck, 5 feet; horizontal diameter.....	22	
Circumference of neck.....	69	
Total height of the monument, according to Mariette Bey.....	65	
Ear.....	6	5
Nose.....	5	10
Mouth.....	7	8
Face, in the widest part across the cheek.....	13	7
Whole length of body.....	140	
Outstretched paws.....	50	

Since Adbullatif's description of its features, the appearance and condition of the sphinx have undergone great changes. The lower part

of the headgear and beard are no more. The features, owing to the iconoclastic propensities of the Kopts and Arabs, are no more "gracefully smiling," as of old; but have a strange, weird expression, amply justifying the Arabic name "*Abu'lhol*," Father of Terrors.

As, regards the date of this monument, Egyptologists do not agree. The latest authority, Budge ('History of Egypt,' Vol. II, p. 49), assigns the period of the Great Sphinx to probably one of the builders of the Great Pyramids, but "it is quite possible," he adds, "that it may be much older." Mariette Bey, Maspero and others attribute it to a much more remote antiquity; to the *Hor-shesu*, the followers of Horus.

The Phœnicians and Greeks imported the sphinx from Egypt and reproduced it in various shapes and forms, of all sizes and of different materials. Some have face and breast of a woman, the body of a winged lion and tail of a serpent, and many other varieties, according to the fancy of the artificer and sculptor. These found their way back to Egypt whence they originated, but in different forms.

SPHYGMOGRAPH, *sfig'mō-grāf*, an instrument for recording the movements of the pulse. The first true sphygmograph was the invention of Vierordt, and has received various improvements. In its most improved form it consists of a small rod which moves vertically up and down, and in so doing communicates motion to a thread passing round two horizontal movable axes, one of which moves a needle that serves as an index, while the other moves a wheel. A pen held in a jointed stalk follows the movements of this wheel and records its motions on a strip of paper, which is passed beneath it by clock-work. The record has the appearance of a more or less irregularly undulating line. At the lower end of the vertical rod is a small plate, rounded on the lower surface, and when the instrument is in use this plate is brought into contact with the skin above the pulse, which is kept in position by a rest supporting the wrist. Before the instrument is set in full operation the position of the pulse is slightly varied until it is ascertained in what position it gives the strongest impulse to the vertical rod, which is indicated by the index-needle on a graduated scale. Obviously, any other form of recording instrument that measures the pulse-beats may bear the name, and some have been invented, but if the test be made directly of the heart action, the name is scarcely appropriate. One of these latter is the electrocardiograph, which measures the cardiac rhythm by electric reaction on a galvanometer principle. Consult Sanderson, 'Handbook of the Sphygmograph.' See PULSIMETER.

SPICE-BUSH, a tall shrub (*Benzoin benzoin*), of the laurel family, frequenting moist woods and the edges of streams. It is conspicuous when leafless on account of its slender branches and olive-green spotted bark, which has an aromatic odor and taste, suggesting to the Indians and frontiersmen, its use as a stimulative tea. Very early in spring, the twigs are covered with tufts of honey-scented, tiny flowers, with yellow calyces. They are either polygamous or diœcious, the male

flowers having many stamens, and the females a globose ovary and several staminodia. The leaves, which follow, are oval or obovate and short-pointed. The fruits are ripe in late summer and are oval drupes, bright red in color, and most disagreeable in flavor. The wood of this shrub is termed spice-wood.

SPICE ISLANDS. See **MOLUCCAS**.

SPICES, a popular name for such plant components, having essential oils of aromatic odor and pungent flavor, as are used direct and blended in for seasoning food; in fresh food nearly always ground, in preserves and pickles always whole. Their companions spread on, as mustard or used only in extracts, as vanilla, are not so reckoned, but as condiments, flavorings, etc. They represent most parts of the plant beyond the wood; cinnamon and cassia are the bark; ginger the root; cloves the flower-bud; allspice (pimento) and pepper, caraway and coriander, the fruit; nutmeg the kernel, mace its wrapper; cumin and dill the seed. All are tropic save the allied group of caraway, coriander and dill, now naturalized in temperate climes—and significantly, not often thought of as "spice"; and all foreign but these and some ginger.

The Spice Trade in History.—The supreme importance of this in revolutionizing and generating modern civilization has never been set forth, because it is not recognized as the leading factor in the old Eastern commerce. Yet not only did it lead directly to the discovery of America and the sea route to the far East, but for centuries it was a chief agent in provoking world wars, determining the rise and fall of states, creating the present status of Europe and the Eastern Question, and even twice remade the world's religious history, first by making Mohammedanism a world power and long after by conditioning the time and early fortunes of the Reformation. The relation of spices to earlier European food which caused this importance was something hardly conceivable at present. All could now be dispensed with at little loss beyond some pleasure; while till recent times they were an exigent need for comfort, health, and with the delicate even life. The winter food of most mediæval English, for instance, was little but meal and salt junk—bacon from lean pigs, beef from scrawny cattle, insufficiently kept by dear and unpurified salt, and so half rotten by spring; washed down by ale without hops. Besides the results in scurvy and endless skin diseases—the source of the old tradition of sulphur and molasses with which women were wont to cleanse children's blood in spring—the meals were not only monotonous and pleasureless but hard for the sick and queasy to force down and bad for them if they did so. Hence in the Middle Ages, perhaps the first call beyond bare nominal aliment was something to make unpalatable food palatable, to tempt invalid appetites and save drooping lives as well as to make eating a satisfaction, and spice became the foremost dream of luxury that was a necessity. The trade to the East, for it was not the only element of that trade, but it was the most vital, the only one that was literally in some measure of life and death, even though the sugar, currants, raisins, almonds, etc., of South Europe and the Levant were also alleviations.

Perfumes, dyewoods, jewels, were agreeable accessories; even drugs could be more or less matched in service: but absence of spices took much of the savor and some of the fibre out of life.

A few of the larger manifestations of the trade will show that the above review is not a fantasy. It is true that the agency of Eastern commerce in causing the Crusades is much overstated, from the modern economic and rationalistic dislike of allowing the old weight to religious feeling. But long before their time, it had assured their coming by creating their foe and need. From the earliest epochs, Arabia had gone through cycles of development corresponding to the routes of trade from the East to Europe. In times of West-Asian peace or the mastery of strong states, this normally went overland, leaving Arabia unfertilized by it, barbarous and disintegrated; when interrupted by war or anarchy, it went around Arabia by the Red Sea and across Suez, creating or redeveloping Arabian coast cities, spreading new needs and consequent political order among the tribes and raising their intellectual status. The Roman-Persian wars of the 6th century thus deflected Eastern trade and made Mohammed's career possible. Later, the trade enriched the Italian cities as the distributors of its goods to central and northern Europe, and the rivalry of Venice and Genoa for Levantine and Black Sea monopoly of the commerce led, first to the Venetian use of the Fourth Crusade to destroy the Byzantine Empire, letting in the Turks on Europe, and then to feuds which neutralized Europe's naval strength against them. What the search for a sea route to India did for the world is familiar. Here, again, the long Portuguese struggle down the West-African coast was primarily not for trade, but to take the Moorish dominion in the rear, unite with Preston John and crush the Moors in the interest of Christianity; but the riches of the spice trade were to be the means to finance this. As to Spain's share in the search, these riches were the direct object. In both cases gold bullion was the special aim; but craving for spices was its most efficient instrument.

The supreme effect on European religion seems fantastic, but is quite simple. The German cities owed their prosperity and sometimes even existence largely to rehandling these goods from the Italian ports. Now the Cape route was so much cheaper, through not having to break bulk and reload and freedom from land tolls, that from its discovery in 1498 the Italo-German route began to lose profit and its factors to be forced out of business. By 1520 the business depression became severe in Germany, and just at this time of pinch came the exactions of the papacy for Saint Peter's. An explosion and revolt were probably not far distant in any event; from economic, political and moral reasons; but hard times acted as the final weight to release the lever.

SPIDER-CRABS, a family (*Maidæ*) of small, spider-shaped crabs represented by many remarkable and strange forms, some of them of large size, which mostly inhabit relatively deep waters. The shell is generally very hard and on the body bears numerous spines and a prominent beaked process or rostrum in front.

The first pair of legs is sometimes larger than the other limbs and always bears pincers and the rudimentary abdomen possesses seven joints. Many species are found along the coasts of the United States. The best-known shallow-water forms on the Atlantic Coast are two species of *Libinia* (*L. dubia* and *L. emarginata*). The former is especially common along the shore south of Cape Cod and has the long rostrum deeply divided in front. They are sluggish creatures which make no effort to escape capture, but depend upon their hard covering for protection. Both species are scavengers and subsist upon all kinds of dead animal and vegetable matter. They conceal themselves by attaching sea-weeds, sponges, etc., to their backs, which growing as though fastened to stones afford them this additional protection. The females, with broad abdomens, are frequently found bearing eggs. The males are larger and often attain a foot in extent. A much smaller flat-bodied species is *Hyas coarctatus*, very common among sponges hydroid and sea-weeds in both deep and shallow water. *Lambrus pourtalesii* is remarkable for the great size of the first pair of legs as compared with the others. It is found in moderately deep water among rocks along most of the Atlantic Coast of the United States.

SPIDER-MONKEY, a South American monkey of the genus *Ateles*, so called from the great length of the limbs, as compared with the body and the extraordinary agility of these animals in racing about the tree-tops; no monkeys excel them in adaptation to an arboreal life, in which they are especially assisted by the length and remarkable prehensile strength of their tails. Their structural resemblance to the langurs and other highly arboreal forms of the Old World is interesting; prominent among these is the absence or rudimentary condition of the thumb, a member which is not of great service in swinging from limb to limb, when the tail serves as an effective means of grasping. The fur is usually black, but in some species gray, in one decidedly brown and in a few Central American species white on the under surfaces and dark above. They go about in small bands, make little noise and are often made captive and become confiding and agreeable pets. Probably the best-known one is the red-faced spider monkey (*A. paniscus*), called coaita in Brazil, which has a rudiment of thumb, is very black and extremely intelligent. Although only about a foot in length its tail is twice as long. Others are the chameck (*A. chameck*), 20 inches in length, the sooty-black white-bellied marimonda (*A. beelzebuth*) of Brazil, the grizzled (*A. grisescens*) and the black, yellow and white variegated spider-monkey (*A. variegatus*), which occurs in the highlands about the headwaters of the Amazon Valley. Consult Lydekker, 'Royal Natural History' (1895); Bates, 'Naturalist on the Amazons' (1863).

SPIDER-SHELL. See SCORPION-SHELL.

SPIDERS, invertebrates of the order *Aranæa*, class *Arachnida*. The English name—spider, spinder, spinner, spinster, the spinning one—comes from the functions for which these creatures have been chiefly distinguished. They are cosmopolitan in distribution; are found in

Greenland and swarm in the tropics. They show great and striking differences in form and in general habits. The spinning habit also differs widely; as one may see, by comparing the round web of a garden-spider, with the snare of the

Outlines of mandibles to show location of poison sac (gl. v.) and the duct (d. cr.) leading to the opening in the fang, cr.

speckled tubeweaver (*Agalena naviæ*), made in hedges, fence-rows, roadsides and angles of out-buildings. These typical differences in habit are commonly united with variations in structure and, therefore, have been made the basis of scientific classification by the eminent Swedish arachnologist, Dr. T. Thorell, following substantially M. Latraille. In no classification can these functional variations be disregarded; but for the use of the general public such an arrangement is most satisfactory and is here adopted. Spiders may be roughly divided into two great groups: (1) Sedentary; (2) wandering. Sedentary spiders live on or in woven habitations and take their prey by means of snares upon or near which they habitually stay. They thus have the distinction, almost unique among lower animals, of resembling man in procuring a livelihood by use of manufactured implements. The wandering spiders wholly or in large part hunt their prey afield. These groups may be thus subdivided:

I. Sedentary Spiders.—(1) Orbweavers (*Orbitelariæ*), which make open webs circular or partly circular in form, composed of radii issuing from a centre and crossed with spirals armed with viscid beads for the capture of insects; these orbwebs are usually vertical, but some are horizontal. (2) Lineweavers or Netweavers (*Retitelariæ*), whose snares are mazes of crossed lines in the midst of which they hang back downward; our common house and barn cobwebs made in corners or rooms are mostly the product of lineweavers. (3) Tubeweavers (*Tubitelariæ*), which live in silken tubes spun in divers situations sometimes with a sheeted snare outspreading from the mouth, as the common speckled tubeweaver that nests in hedges, borders and grass. (4) Tunnelweavers (*Territelariæ*), making tubular nests, usually silk-lined, often with extensions above ground; the trap-door spider (*Cteniza californica*) is our best-known type.

II. Wandering Spiders.—(5) Citigrades (*Citigradae*), many of which, as the lycosids, burrow in the ground. (6) Laterigrades (*Laterigradae*), which live upon plants and among rocks, getting their name from their rapid side-wise movements. (7) Saltigrades (*Saltigradae*), jumping-spiders, vivacious creatures, with large, bright eyes, living on plants and walls, etc., over which they move by frequent jumps and among which they make tubular nests of thick white silk.

This arrangement Professor Thorell subsequently modified, dividing the order *Aranea* into two suborders, *Tetrapneumones*, containing (1) the *Territelariæ*; (2) the *Dipneumones*, embracing all other tribes. M. Eugene Simon, a distinguished French araneologist, retains the two suborders, which he names (1) *Aranea theraphosa*, composed of three families, of which the tarantula and trap-door spider are types; and (2) *Aranea vera* (38 families), containing all other spiders, divided into two great groups or sections, *Cribellate* and *Ecribellate*.

Structure.—The early entomologists included spiders among insects and in popular thought they are still so ranked; but they are widely separated therefrom. The most noticeable differences are: spiders have eight legs; insects, six; spiders have the head united to the thorax, insects separated therefrom by a neck; spiders have simple eyes, insects have compound. The spider's body is divided into two parts, cephalo-thorax and abdomen, united by a straight pedicle or stem. Two mandibles or jaws are attached to the face, each having a hollow fang folded up within a groove when

at rest like a pocket-knife's blade within its handle. A small opening in the fang communicates through a minute duct with a pear-shaped

poison-sac, in the upper part of the mandible and head. The poison, as in the case of snakes, is forced out when the spider strikes its victims. On either side of the mandibles is a six-jointed palp, shaped like the legs, which, besides other uses, serves to hold and turn the prey when swathing it or feeding upon it. The eight legs are attached to the cephalo-thorax, are seven-jointed, covered with spines, bristles and hairs, the tarsal joint ending in a foot having two or three claws constructed for grasping and handling delicate threads. The second main part of the spider's body is the abdomen, which while generally ovate greatly varies in form; being globular, subtriangular, cylindrical; sometimes flat, sometimes convex above. The ventral surface is flat or slightly concave. The integument is commonly soft, but sometimes leathery; in many species it is hairy; in others nearly

naked and glossy; in some bordered with sharp, hard, spinous processes or conical tubercles at the base, which for the most part overhangs the cephalo-thorax. The pedicle or stem uniting these two principal parts of the body is a short cartilaginous tube through which pass the organs of nutrition and circulation. This partial description, with the accompanying figures, will give a sufficient general idea of the structure and appearance of the most common species.

The mature male is most readily distinguished from the female by the bulbous shape of the terminal joints of the palps, which often assume involved forms that serve as good specific characters. Some times, as in certain orb-weavers, the male is so much smaller than his mate that the disparity seems ridiculous. Wooing under such conditions is a serious undertaking. One will see several diminutive courtiers in attendance at the outer courts of the snare of our native species, the orange and the silvery *Argiope* (*A. aurantium*, *A. argyraspis*); and not infrequently dead and juiceless skele-

tons may be seen hung up thereto in silken swathments, like scalps upon a savage's wigwam.

Habits.—Gravid females differ largely in their modes of caring for their eggs and young. Most species enclose the eggs in a silken sac,

Face of *Epeira mb*, mandibles, with the fangs, fx, and fangs, lg; es, eye space; v, vertex; cp, clypeus; MR, mid-rear eyes; SR, side-rear; MF, mid-front; SF, side-front.

which is protected in various ways. Orange *Argiope* spins a large pyriform cocoon with a tough, nearly waterproof case, lined inside with yellow floss, which encloses an ovate mass of brown silk, within which are the eggs numbering as high as a thousand or more. This is hung upon bushes, stayed and surrounded by sundry braces and cross-lines. The labyrinth spider (*Epeira labyrinthea*) puts her eggs into several silken discs strung together in a bead-like row, which is swung within the thick maze that surrounds the leaf-thatched domicile that overhangs her orb. Many orbweavers spin their cocoons in angles of cornices, under bark, in cracks and crevices, knot-holes and sheltered

Female (upper figure) and male (lower figure) of *Nephila nigra*, shown one-half natural size.

openings of all sorts. A bit of loose bark on an old tree is a favorite cocooning place for many spiders; there the speckled tubeweaver will

often deposit her eggs within several wraps of silk, all overlaid with bark pellets gnawed from the tree. Some of our familiar line-weavers, as *Theridium tepidariorum*, put their eggs into several brown sacs which they keep near them within their netted cobwebs, on which the spiderlings hang when they are hatched. Many

tubeweavers and laterigrades spin a tough disc, white, gray, mottled or pinkish, against various surfaces, especially on or under stones. Most species die shortly after cocooning and the young are left to the nurture of nature. Others have some sort of care over the spiderlings when they appear and until they leave the home bounds. Among ground-spiders (*Lycosida*) one notes the interesting habit of tying the round egg-bag to the spinnerets and carrying it around until the younglings come out, when they mount the mother's back and are borne around clinging thereto until they disperse. A mother with a hundred babies piled upon her body as she runs over the ground is a grotesque spectacle; but the oddity vanishes in the light of mother-love. At least one species, the European water-spider, cocoons under water within her diving-bell-like domicile. This is but a glance at the varied forms which maternal instinct takes among spiders to perpetuate the race.

Beneficial Uses.—One needs to give good heed who would know how large a part spiders have in the economy of nature. They are among the most numerous of our fellow-tenants of the earth. A fair idea of the myriads that live near us may be had on a dewy morning of late summer or early autumn. Glancing over the fields and along the country roadsides one will see their webs, disclosed by the minute beads of mist caught by the delicate threads, literally covering the low herbage. Turning the eyes to bushes and trees, the branches, twigs and leaves are seen to be meshed with spinning work. In short, the whole landscape is overspread with the tents and meshes of the aranean hosts. Other hosts could be found by raking amid fallen leaves and earth-litter and searching beneath stones, logs and rubbish, in hollow trees, post-holes and crannies, under ledges and along the water side. There is scarcely a spot, indeed, where some species of spider may not be found. The problem of commissary supplies for this innumerable army is an important one, and its

consideration opens up a strange contradictory phase of human nature, or perhaps one should say of human ignorance.

The popular prejudice against spiders has been so long fixed that it is hard to overcome it, but is yielding before the better knowledge of natural objects and sympathy therewith that now prevail. The prejudice is perhaps largely due to erroneous views of their ugliness and dangerousness. The species frequenting cellars and outhouses are dark colored and at first glance somewhat ungainly. But to judge the race by these would lead one as far astray as to judge all birds by buzzards and crows. In truth, some spider species rival butterflies and beetles in brilliancy of color. And these are not tropical forms alone, but are among our indigenous species and may be found in most parts of America by searching fields, bushes, bosky brook-sides, the edges of woods and open places therein. Delicate greens, pink, ruby, scarlet, orange, yellow, brown, gray and metallic hues, silver and green especially, abound, and give remarkable beauty to the outer robing of our native fauna. Exotic species are even more brilliant.

Yet more erroneous is the popular view of the spider's noxious and injurious character. That a few species may and occasionally do inflict a wound that may cause suffering and under peculiar conditions even death is doubtless true; although it is nearly impossible to verify current reports of injury and death caused by a so-called "black spider," which, as it commonly turns out, had simply been seen somewhere near the victim. That insects inflict wounds which may be serious under certain unfavorable conditions is well known, and the possibilities for great damage to the human family by flies and mosquitoes is now established. But spiders may be ranked among the least dangerous to man of the small and most familiar invertebrates. The writer has been struck by large lycosids (ground-spiders) and has compelled one of our largest orbweavers to wound him, without more serious consequences than the prick of a pin. A mosquito's puncture, on the contrary, causes a painful hurt,

with an inflamed area the bigness of a silver dollar surrounding the central white swelling. This will show that personal idiosyncrasies are factors in the danger to man of a spider wound,

as of an insect's. Admitting the worst, however, the credit side of the spider account is so large that the reverse is scarcely worth mention. Insects are known to be serviceable in the fertilization of many plants. The bee has been domesticated for the edible product of her cells and the silkworm for its cocoon fibre. But beyond these and a few other exceptions the insect hordes are among our most destructive domestic foes. Farm, garden, orchard and plantation can be profitable only by vigilant and unremitting warfare upon these destroyers

American works the student may obtain needed help. Among them are 'Spiders of the United States' by Professor Hentz, the father of American araneology; Dr. McCook's 'American Spiders and their Spinningwork,' 3 vols., folio, profusely illustrates structure and habits and gives classification of Orbweavers; the studies by Prof. Geo. W. and Mrs. Elizabeth G. Peckham of general habits are most interesting and their work on the 'Attidae' is quite complete; 'The Common Spiders of the United States' by J. H. Emerton is a good popular treatise; 'Catalogue

whose inroads cost the nation hundreds of millions yearly. But spiders injure no food-plant or other product of human industry. In fields and groves, orchards and outhouses they are not only absolutely innocuous, but are engaged in ceaseless warfare upon the enemies of man's prosperity, comfort and health. Their chief food is insects, and day and night they pursue that function which nature has assigned them and keep in check the myriads of insects that otherwise would overwhelm us. It is doubtful if civilized man could successfully cultivate or even inhabit the earth, if it were not for these despised benefactors, unless nature were to provide some other agency to hold even the balance of helpful and harmful life. Even when spiders enter our homes and spin their cobwebs in our porches, halls and chambers, they come upon the wholesome errand of clearing our premises of irritating and dangerous guests. It is pitiful that these benefactors of our race should be the subjects of unsparring obloquy and hate and should be slain at sight without compunction.

Bibliography.—The literature of spiders is too abundant to be here cited; but from several

of the Described Araneæ of Temperate North America,' by the late Dr. George Marx of the Smithsonian Institution, is valuable; Nathan Banks of the National Museum, Washington, has written some important papers, as also has Prof. Thos. Montgomery of the University of Texas, Austin. Among foreign works one should know the 'Histoire Naturelle des Araignées' of M. Eugene Simon. Among British authorities consult 'Blackwell's Spiders of Great Britain and Ireland' and the works of Dr. Pickard. Emerton, J. H., 'The Common Spiders of the United States' (Boston 1902); Fabre, J. H. C., 'The Life of the Spider' (New York 1913); Keyserling, E., Graf, 'Die Spinnen Amerikas' (Vol. IV, Nürnberg 1892); McCook, H. C., 'American Spiders and their Spinning Work' (3 vols., Philadelphia 1889-93); Petrunkevitch, A., 'A Synonymic Index Catalogue of Spiders of North, Central and South America, etc.' (in American Museum of Natural History Bulletins, Vol. XXIX, New York 1911); Warburton, C., 'Spiders' (Cambridge 1912).

HENRY C. MCCOOK,
Author 'American Spiders and Their Spinning Work.'

SPIDERWORT, any plant of the genus *Tradescantia*, or (by extension) of the family *Commelinaceae*. The spiderworts are perennial, succulent, somewhat mucilaginous herbs, having linear or lanceolate leaves and showy reddish or blue flowers in umbel-like cymes, subtended by bracts. *Tradescantia virginiana* is a species native to the Middle Atlantic States, but often found farther north in cultivation or escaped from gardens. It has stems often in clusters and about a foot high; the leaves very narrow, either glabrous or slightly pubescent, as long as the stem and of a bright green color. The large corollas of three petals are sky-blue, the villous pedicels being declined until in bloom. The sepals are broad and herbaceous. The anthers are large, crescent-shaped and golden, and the filaments are heavily bearded. A South American spiderwort, *T. fluminensis*, is better known under the title of Wandering Jew. It has similar flowers and broadly lanceolate leaves and is very easily propagated by cuttings, growing often in water only.

SPIEGELEISEN, spē'g'l-ī'zēn, a white cast iron originating in Germany, made from specular iron ore, or hematite, containing a large percentage of carbon and manganese. Being remarkably free from impurities, as phosphorus, sulphur, silica, it is largely used in the Bessemer process of steel-making for the purpose of reintroducing carbon. It reduces the iron oxide and is itself subject to oxidation.

SPIELHAGEN, spēl'hā'gēn, Friedrich, German author: b. Magdeburg, 24 Feb. 1829; d. 1911. He studied at Berlin, Bonn and Greifswald, turned from an academic career to literature, made some translations from French and English, including one of 'Amerikanische Gedichte' (1856; 3d ed., 1871), and after publishing two sketches that attracted little attention, became well known through his 'Problematische Naturen' (1860), in which he advocated the advanced liberal politics of his time. His 'Sturmflut' (1876), based on the financial crises in Berlin following the Franco-Prussian War, is worthy of comparison with this. He wrote a great number of optimistic and sometimes extravagant novels, having a preference for social problems. His books are often truly voluminous and frequently somewhat grandiose, but display a certain energy of treatment in dealing with what the author believed important questions of the time. See **PROBLEMATISCHE NATUREN**.

SPIERS, spērz, Richard Phené, English architect and archæologist: b. 1841. He was educated at King's College, London, and the Ecole des Beaux Arts, Paris, and is master of the Architectural School and surveyor of the Royal Academy. In addition to editing Pugin's 'Normandy' (1870) and Fergusson's 'History of Architecture' (1863), he has written 'Architectural Drawing' (1887); 'The Orders of Architecture' (1902); 'Architectural Essays on Sassanian Architecture'; 'Domed Churches in Perigord'; 'Architecture, East and West,' etc.

SPIGELIA, spi-jē'lī-a, a genus of annual and perennial herbs of the order *Loganiaceae*, of which about 35 species are American. They have opposite, membranous leaves and terminal spikes of yellow, red or purplish flowers. The

best-known one, pink-root or worm-grass (*S. marilandica*), is native from New Jersey to Wisconsin and southward to the Gulf States. It is valued in hardy garden borders because of its handsome, red, tubular, yellow-throated flowers which appear during mid-summer and also because of its easy culture in rich, friable, loamy soils. Its roots have been used medicinally.

SPIKENARD, a North American herb. See **ARALIA**.

SPINA BIFIDA, cleft spine. See **TUMOR**.

SPINACH, spin'āj, or **SPINAGE**, an annual herb (*Spinacia oleracea*) of the family *Chenopodiaceae*. The plant is probably indigenous to southwestern Asia, whence it has been carried to all cool climates throughout the civilized world for use as a potherb. The original species has a rosette of arrow-shaped radical leaves, from the centre of which a flower-stalk is developed two to three feet tall and bearing small axillary clusters of dioecious flowers followed by seed-like fruits (akenes). In cultivated varieties the form of the leaf is various and its size and thickness greater than in the wild. Only one other species of the genus is now recognized (*S. tetrandra*) but is not cultivated. There are, however, groups of varieties which have been given specific names mainly because of the form of the fruits. Though the popular names are retained in the trade the plants are considered one species. The original form is not known. Spinach thrives in light, well-drained, loamy soils and always gives best returns when abundant nitrogenous food is readily available. It is easy of cultivation. The seed may be sown in early autumn in the North and covered during the winter with loose straw or marsh hay, free from weed-seeds. In spring the mulch should be removed very early. Early spring sowing may be done but, since the plants produce smaller, fewer and poorer leaves, and are prone to develop a seed-stalk at the approach of warm weather, the planting season in spring must be curtailed. About eight weeks usually elapse between sowing and gathering the plants except when the crop is wintered. In field practice spinach is usually sown in beds about 10 feet wide made by plowing several furrows toward a centre and leaving dead furrows between the beds for surface drainage. The seeds are sown in drills about 15 inches apart and the ground kept cleanly cultivated. Since the crop is of short duration it is generally used prior to or after summer-maturing crops. It is, however, also frequently sown between the rows of other crops. Immense quantities of spinach are grown in the South, especially upon the Atlantic seaboard for the Northern markets, and except for home use the cultivation of the crop under cold frames is now little practised in the North. The plants are gathered when dry with some of the root attached, trimmed of dead leaves and shipped in tightly packed barrels or crates.

SPINAL CORD, the posterior or inferior portion of the cerebro-spinal axis, entirely located in the spinal canal. In those animals which stand upright it may be termed the lower portion. The spinal cord is directly continuous with the medulla oblongata (q.v.) and, varying with different animals, it extends practically the

length of the spinal canal, giving off numerous paired spinal nerves (q.v.) and terminates by breaking up into a series of terminal nerves, the so-called cauda equina. With reference to its length and thickness, its divisions and arrangements, both internal and external, considerable variation exists in different animals. (See ANATOMY, COMPARATIVE). In man, however, the spinal cord comprises all that portion which lies between the cauda equina and the decussation of the pyramids in the medulla. It lies within the bony framework of the spine, covered on the outside by a thick membrane, the dura mater, which is continuous with the dura mater of the brain. Within this is a thin delicate layer of tissue, the pia mater, which covers the cord closely, being continuous with the pia mater of the brain. Between the dura and pia a certain amount of cerebro-spinal fluid is found, which serves as a protection-sheath. Passing out and coming into the cord are the paired motor and sensory nerves that carry motor impulses to all the muscles of the body below the head and sensory impulses to the brain from all the sense organs of the skin, mucous membranes and viscera. In simple language it is a large cable which carries incoming and outgoing messages. The incoming messages come through various organs of sense, the stimuli come in through receptors, they then travel in nerve fibres, enter the cord, form connections, etc., with the brain or other nervous centrals and outgoing messages travel down to make effective action in the environment. The general shape of the spinal cord is cylindrical. It is slightly flattened front and back and tapers at its caudal end into a long thin strip, the filum terminale. In its course it shows two enlargements, the cervical and dorsal enlargements, corresponding to the location of increased amounts of nervous tissue that go and come from the upper and lower extremities. The length of the cord proper, apart from its terminal filament, averages only about 18 inches; it, therefore, falls short several inches of filling the entire spinal canal. It is about one-half inch in width at the widest part and weighs in an average adult about one pound. The spinal cord is nothing but a collection of nerve ganglia and nerve-fibres, but in the human cord these are not as simple in their arrangement as in the nervous cords of insects, for instance. The cord preserves its bilateral symmetry, but its metameric symmetry is much modified, particularly in its internal structure. Thus the spinal cord consists of nerve-cells and nerve-fibres like all other parts of the nervous system. It is divided almost into two halves by deep fissures in front and behind; and there are several secondary fissures that further subdivide the cord into segments corresponding somewhat to its anatomical arrangement. In order to understand somewhat of this anatomical arrangement it is important first to trace the different fibre-tracts that go up and down the spinal cord and which make up its white matter. The first nerve-fibres to develop are sensory. These collect into bundles and, through the posterior spinous processes, pass into the cord and constitute two bundles of fibres, the columns of Gall and the columns of Burdach. These columns are at first very small, but as they continue to receive more and

more fibres passing upward they become larger. After their entrance into the cord the sensory fibres give off many collaterals, making extremely complicated anatomical connections with the different segments of the cord. One set of these collaterals, however, makes a distinct bundle of fibres, which has been called the column of Gowers, or ascending lateral tract. All three of these fibre-tracts carry sensory impressions from the surface of the body to the brain; they constitute the sensory neuron-paths. The column of Gowers is known to carry pain-sensory stimuli. These sensory neuron-paths terminate in the sensory areas (q.v.) in the brain, having numerous interruptions or stations, on the way up. The typical sensory neuron-path is made up of three or four of these stations. The first ganglionic centre is in the posterior ganglia; the second is in the medulla, constituting the nuclei of the columns of Gall and Burdach; the third is in the optic thalamus and the fourth is in the cortex of the brain. As to the part of the cortex, it varies according to the character of the incoming stimuli: gravity stimuli are mostly located in the cerebellum, sight stimuli in the occipital lobes, sound stimuli in the temporal lobes, where the sensations for liver, spleen, kidney, heart, etc., are, is still under discussion. Passing down from the brain a large number of motor tracts make up the larger part of the remaining white matter of the cord. The most important of these bundles are the direct and indirect or crossed pyramidal tracts. The descending anterolateral tract and direct cerebellar tract are other smaller fibre-masses. Still other minute fibre-bundles are found in the cord, but their description belongs to more extensive treatises. The main function of these descending tracts is to carry motor impulses down from the motor area to the gray masses of nuclei located on the interior of the spinal cord. From these spinal centres the impulses are transmitted to the motor nerves which pass out the entire length of the cord, from in front, where they later bend backward and join the sensory fibres and together form mixed nerve-trunks. The motor nerves finally terminate in the muscles by specially modified muscle-plates. As the nuclei of the columns of Gall and Burdach in the medulla were the first ganglionic terminals of the sensory neuron-chains, so the gray masses in the anterior columns of the cord are the first ganglionic terminals of the motor neuron-chain. If the spinal cord be cut across, these ganglionic masses appear on the cut surface as a gray letter H, or as a butterfly-wing, according to the region where the cut is made. In these wings certain definite groups of ganglion-cells may be made out, running short distances in and down the spine. These constitute definite ganglionic centres for certain muscle-groups, and their destruction causes the well-known spinal paralysis of children. Throughout the entire length of the spinal cord there is a small cavity around which there are bridges of fibres connecting the two halves of the cord. Thus the spinal cord is seen to represent a mass of cells and fibres, of vastly complicated structure, and subserving all of the nervous functions of the muscles of the skeleton and of the viscera below the diaphragm, save the stomach. The

spinal cord is in intimate connection throughout its entire length with the sympathetic nervous system. Any interruption in the spinal cord interferes with the carrying capacity of its fibres and cells. There then results disease of the spinal cord the symptoms of which will differ according to the place where the interruption takes place. As the pathways of the different kinds of sensation messages and motion messages are extremely complex they cannot all be spoken of here. Only some of the more striking types of loss will be spoken of. If the entire cord is cut across, as happens in broken back from diving into shallow water, from bullet wounds of war, or sometimes from a tumor of the spinal cord, or an inflammation, there results a paralysis of all motion below the place where the injury takes place. If in the upper neck region the paralysis is of the entire body below the neck. If the injury is lower down the lower extremities alone are involved with such portions of the trunk as lie below the site of the injury. All above the site of the lesion is a loss of sensation. This would naturally follow from what has been said that the pathways are carrying sensory messages up and motor messages down. An incomplete section of the spinal cord introduces a number of complicated results which only the nervous specialist can analyze. He is like a telephone expert. He is a trouble hunter on the line and from the symptoms which the patient shows he is able to accurately locate the place where the interruptions are occurring or have occurred.

In some disease processes localized parts of the spinal cord are picked out by the process and a limited type of injury takes place. Thus in the disease known as infantile paralysis [poliomyelitis] the virus of the disease chiefly involves the connections of the motor pathways as they make a switchboard connection with the muscle groups in the anterior horns of the spinal cord. This results in a partial or complete paralysis of one or more groups of muscles. Sometimes the sensory parts of the cord are cut off or diseased. This cuts off information from switchboard operators higher up and various types of loss of feeling, inability to localize, inability to know what one is doing with one's muscles, etc., results. A great number of complicated troubles can result and bring about the clinical pictures called syndromes, in neurology, such as locomotor ataxia, syringomyelia, multiple sclerosis, paraplegia, muscular atrophies, etc., which must be consulted in a work on diseases of the spinal cord or diseases of the nervous system. Consult Barker, 'Nervous System' (1901); Dejerine, 'Anatomie du Systeme Nerveux' (1901-04); Van Gehuchten, 'Systeme Nerveux' (1903); Spalteholz, 'Anatomy Atlas' (1904); Winkler, 'Manual de Neurologie'; Jelliffe and White, 'Diseases of the Nervous System' (3d ed., 1919). See BRAIN; NERVOUS SYSTEM, EVOLUTION OF THE; REFLEX ACTION.

SMITH ELY JELLIFFE, M.D.,

Editor 'Journal of Nervous and Mental Diseases.'

SPINAL CORD SURGERY. The surgery of the spinal cord has been much advanced during the last decade and at the present time clear indications exist for operative interference.

In injuries of the spinal cord due to fracture of the vertebra or bullet or high explosive wounds, operative interference should be done only if the spinal cord has not been completely crushed. If the X-ray gives evidence of pressure on the cord from fractured bone or foreign bodies, a laminectomy should be performed. If there is doubt as to whether the lesion is a complete one, i.e., involving the complete thickness of the cord, the patient should be watched for symptoms to give evidence that part of the cord is still functioning. Spinal cord surgery has had its greatest triumphs in the removal of tumors pressing upon the cord, and if the condition is recognized early the patients can be entirely relieved of their symptoms. Inflammatory diseases of the spinal cord sometimes demand operative interference, especially in those cases in which the disease is slowly progressing and at a definite level of the cord. Operations upon the spinal cord are sometimes required for the condition of the nerve roots. The technic of spinal operations has been much simplified. In the large majority of instances, in otherwise healthy individuals, the dangers of operation are very small. In the operation, known as laminectomy, the spinal canal is opened by the removal of its posterior wall, that is, by the removal of the spinous processes and laminae forming together a posterior arch of each vertebra. The functions of the vertebral column are fully regained after spinal operations. The mortality of the spinal operation itself, in otherwise healthy individuals, should be no more than 5 per cent, which is a small mortality for a major operation of this kind.

CHARLES A. ELSBERG, M.D.

SPINAL NERVES, the paired nerves which arise from and pass into the spinal cord (q.v.), and which are distributed to the various muscles of the body and come from the various sense-organs, skin, intestines, bladder, etc. The spinal nerves are so named in contradistinction to the cranial nerves, or those which originate from or pass into the brain itself. From the spinal cord of man 31 pairs of spinal nerves arise. They pass from and enter into the spinal cord and spine through the intervertebral foramina, or openings between the bodies of the vertebrae, the motor part of the nerve passing out in front, the sensory part coming in from behind. Eight pairs are cervical; 12 are dorsal nerves, also named thoracic; five are lumbar, five sacral and one coccygeal. Each spinal nerve is formed from two portions, an anterior or motor, and a posterior or sensory. The posterior root has a nerve-mass or ganglion, which is wanting in the anterior. The fibres of the anterior roots are motor in nature; that is to say, impulses travel by these roots outward from the cord or brain to the body. The fibres of the posterior roots are sensory: impulses are conveyed by these fibres to the cord or brain. The anterior and posterior fibres unite just beyond the nervous ganglion to form a single nerve-trunk, in which the two sets of fibres are indistinguishable. See ANATOMY; BRAIN; NERVOUS SYSTEM, EVOLUTION OF THE; SPINAL CORD.

SPINDLE-TREE, a name originally applied to an European species of *Euonymus*, shrubs belonging to the *Celastraceae*. The

American species have more or less four-angled and winged stems, with petioled entire or serrate leaves and regular, perfect four to five-merous flowers in axillary cymes. They open in early summer and are small and inconspicuous and greenish or purplish in color; they are succeeded, however, by very brilliant fruits or pods, which are several-celled, lobed or angled and which, when mature, open, showing the somewhat fleshy red arils which have grown up from the base of the seeds and now enclose them. The fruits remain on the tree during the winter, so that these shrubs are often cultivated in ornamental shrubbery. *E. europæus* is called spindle-tree, because its hard, close-grained, white wood was once esteemed as a material for spindles, musical instruments and netting needles and is still used for skewers and in turning. It is a glabrous shrub, with broad and shining leaves and deeply four-lobed, smooth pods which have been employed as a dye-stuff. One of our most handsome shrubs in autumn is the burning bush, or wahoo, *E. atropurpureus*, with crimson and scarlet lobed capsels. *E. americanus* is the strawberry-tree, a low bush, with oval leaves and a crimson capsule, scarcely lobed, but covered with pointed warts and disclosing scarlet arils. The *E. obovatus* is similar in fruit, but has a trailing habit and obovate leaves. The foliage of a Japanese species (*E. alata*) turns to a brilliant rose pink in autumn.

SPINE, the backbone of a vertebrated animal. See ANATOMY; OSTEOLOGY; SPINE, PATHOLOGICAL CHANGES IN; TUBERCULOSIS.

SPINE, Pathological Changes in. The odontoid process of the axis of the spine presents two articulating surfaces, one in front, of an oval form, for articulating with the atlas, and another for the transverse ligament, the latter frequently encroaching on the sides of the process. Serious displacement at this point of articulation causes instant death, due to pressure and injury of the cord and nerve-trunks. The vertebral column quite frequently sustains fracture from an indirect violence which tends to produce overexertion on one flexion of its normal curvature. Tuberculosis of the vertebral articulations or Pott's disease is an affection of the spine. At birth there are no curves in the infant's spine, but as the child assumes the sitting or erect posture, curves which are recognized as the normal vertebral curves are developed. Weak muscles, careless postures and paralysis of special groups of spinal muscles are causes of spinal curvature. Scoliosis is lateral curvature, that is, with the convexity of the curve to one side. Cyphosis, or humpback, is the form in which the convexity of the column is increased in a posterior direction. Lordosis, or hollow-back, is a spinal deviation in which the convexity of the curve is forward. In old age the spine is apt to shorten owing to shrinking of the gristly formation between the vertebrae. Inflammation of the cord rarely gives rise to pus, but a few cases have been described. The suppuration is necessarily micro-organismal in origin and as a rule it is either due to some septicæmia or traumatism, or secondary to purulent meningitis. The spinal cord (q.v.) is influenced by diseased conditions of other parts of the body. It is the centre for all the degenerative disorders of

the nervous system, such as locomotor ataxia, degenerative spastic paraplegia, primary lateral sclerosis, etc. The chiropractics have made special study of the spine and the nerves passing through its articulations. See CHIROPRACTIC.

SPINE-FOOT, a genus of lizards (*Acanthodactylus*), so named from the spinous appearance of the toes, which are "keeled" beneath and possess fringed edges. A familiar brown species (*A. vulgaris*) occurs from Spain and Morocco eastward to northern India.

SPINEL, an isometric mineral of many colors, almost always in octahedral or dodecahedral crystals. Octahedral twins are so common as to give the name "spinel twin" to this form (see explanation under MINERALOGY). It is characterized by a hardness of 8, which is exceeded by only three minerals, diamond, corundum and chrysoberyl, and is equaled by but a few. It is brittle; fracture conchoidal; specific gravity, 3.5 to 4.1; lustre vitreous; streak white; transparent to nearly opaque. Essentially it is a magnesium aluminate or a compound of the oxides of magnesium and aluminum, these metals being at times in part replaced by iron and, in the variety picotite, also by chromium. The varieties are distinguished by differences both in color and composition. The red variety is often transparent and is known as ruby spinel (q.v.) or balas ruby. Rubicelle is yellow or orange-red; ceylonite or pleonaste is dark-green, brown or black and nearly opaque; chlorospinel is grass-green. Blue and yellow varieties are also found and sometimes yield choice gems. Its most noteworthy occurrences are in the gem gravels of Ceylon, Burma and Siam, in the ejected blocks of Vesuvius and in the limestone belt of Orange County, N. Y., and Sussex County, N. J.

SPINEL GROUP, an important group of isometric minerals, usually included among the oxides, though chemically they are oxygen salts. The group embraces the closely related aluminates, spinel, hercynite and gahnite; the ferrates and manganates, magnetite, magnesioferrite, franklinite and jacobine; and the metachromite, chromite. Their general formula is $R''R'''O_4$.

SPINELLO, spē-něl'ō, Di Luca (called SPINELLO, ARETINO), Italian painter: b. Arezzo, 1333; d. there, 1410. His principal frescoes were done for the sacristy of the church of Saint Miniatus near Florence, for buildings at Pisa, Siena, Arezzo and for the municipal buildings of Sienna (a series illustrating the Italian wars of Frederick Barbarossa). Spinello enjoyed a great reputation in his own day, being compared, and by some preferred, to Giotto, whose style his own in some respects resembles. His 'Virgin and Child' sold in 1889 for \$3,725.

SPINET, a stringed instrument invented about 1490, formerly much in use, but now superseded by the pianoforte. It was somewhat similar to the harpsichord, and like that consisted of a case, sounding-board, keys, jacks and a bridge. The spinet was smaller than the harpsichord and contained two or three sets of jacks (small oblong slips of wood, with crow-quills attached for striking) and strings so dis-

posed and tuned as to admit of a variety of stops, while the former had only one set of jacks and strings and consequently only one stop. See PIANOFORTE.

SPINGARN, Joel Elias, American educator: b. New York, 17 May 1875. He was graduated from Columbia University in 1895, became an instructor and in 1909 was professor of comparative literature; has published 'A History of Literary Criticism in the Renaissance' (1899); 'The New Criticism' (1911); and other works of literary criticism.

SPINIFEX, or PORCUPINE GRASS, a perennial grass (*Triodia irritans*) which grows on otherwise barren dry ground in Australia, forming tussocks through which horses and men find difficulty in progressing because of the uncertain footing and because the spiny edges of the hard leaves cut the clothing or feet.

SPINNER, Francis Elias, American financier: b. German Flats (now Mohawk), N. Y., 21 Jan. 1802; d. Jacksonville, Fla., 31 Dec. 1890. He was apprenticed to a confectioner and then to a saddler, but in 1824 became a merchant at Herkimer, N. Y. He was deputy sheriff of Herkimer County in 1829-34, sheriff in 1835-37, was active in the militia where he gained the rank of major-general and in 1838-39 was State commissioner for building the State lunatic asylum at Utica. He was connected with a bank in Mohawk for 20 years as cashier and as president, was auditor and deputy naval officer in the naval office at New York in 1845-49, and in 1855-57 was a Democratic member of Congress. He was one of the original members of the Republican party, was re-elected by it to Congress in 1856 and in 1858, and was appointed United States treasurer by President Lincoln in 1861, a post which he occupied until 1875. He was the first to suggest the employment of women in the government offices and carried his point, though against much opposition. His name became during his long term of office the synonym of integrity and his designedly singular signature on the "greenbacks" of the United States was the most familiar autograph in the country.

SPINNING, the process of twisting into fine threads of uniform size fibres of cotton, flax, wool or other fibres for weaving purposes. The process was performed by hand from early Egyptian times with the distaff and spindle, the distaff being a stick or staff on which a mass of carded raw material called a roving was loosely bound and the spindle being a smaller round stick, usually weighted, to which the thread was attached and with which it was twirled into a thread or yarn by adroit manipulation. The art of spinning thus came to include two distinct operations: the drawing out and evening the fibre which was to form the thread; and the twisting of it. In hand-weaving the first was done by the fingers of the left hand; the second by the right hand.

The spinning-wheel to revolve the spindle, attached to its frame, was an improvement on the manual method, introduced from India into Europe during the 14th century and thence to America in the 17th century. Its use did not begin to be displaced until the middle of the 18th century, and it was still to be seen in operation at the beginning of the last quarter of

the 19th century, in many provincial places untouched by railways, throughout Europe and other parts of the world. The operation usually performed by young women gave rise among English-speaking people to the word "spinster."

The India wheel was comparatively large and the operator stood at her work, walking away and back as the forming of the thread seemed to require. A wool-spinner working continuously would thus travel 20 miles a day. The next development was the "Saxony wheel" or flax wheel, invented in Nuremberg about 1530. This wheel was much smaller in diameter and operated by a treadle, the spinner sitting at her work. The driving-cord of the Saxony wheel was in two loops, one passing around the pulley of the spindle and the other around the pulley of a bobbin or reel on which the yarn was wound as it was spun. Later two spindles were in use on the Saxony wheel by expert spinners, who thus doubled the usual amount of thread in a given time. With the improvement of the loom, so that its output was quadrupled, the demand for yarns was suddenly increased beyond the capacity of the hand spinners. Invention was thus stimulated and in 1738 two spinners, John Wyatt and Lewis Paul, devised and patented a method of drawing out and evening the fibre preparatory to twisting, by means of rollers revolving upon one another. For some unexplained reason this mechanism failed to come into popular use in the spinning trade until 30 years later, when the idea was adopted by Richard Arkwright and embodied in his throstle machine. In quick succession, at the beginning of the last third of the 18th century appeared Hargreave's spinning jenny, an improvement on the double-thread producing Saxon wheel; Arkwright's throstle machine, or roll-drawing spinning machine; and Crompton's mule-spinner, three inventions which revolutionized the art of spinning. Although many important improvements have been made since in constructive details, the general principles of all modern spinning machinery are those of these three inventions.

The spinning jenny invented by James Hargreave's in 1767, in its simplest form, resembled a number of spindles turned by a common wheel or drum which was worked by hand. It stretched out the threads as in common spinning of carded cotton, eight at a time, but this was soon improved upon and with the application of power as many as 80 could be spun as easily. The drawing was done by a movable carriage on a track which simulated the movement of the walking spinner at the India wheel.

The throstle or roll-drawing spinning machine, patented by Arkwright in 1769, accomplished its object, the drawing of the rovings, through the action of successive pairs of rollers, each pair in advance of the others and moving at different rates of speed. The first pair to receive the sliver compressed it and passed it to the second pair, which revolved at a greater speed and thus pulled it out to exactly the number of times greater length that their revolutions exceeded those of the other pair. As the roving issued through the last rollers of each machine, it was received on spools or reels, calculated to hold a given quantity; and these were transferred to the spinning-frames, which resembled the roving-frames. As the roving unwound from the

but his conception is very different from the ordinary theological one. In the first place the world is not regarded as dependent on the will of God, but as the necessary result of his nature or essence. Everything necessarily follows from the nature of God, just as the properties of the triangle or circle follow, from the nature of these figures. The bond which necessarily unites all of the parts of the universe to the common centre or substance, and thus to each other, is not causal in the usual sense of that relation, but rather logical. God is the underlying ground from whose nature or essence all things proceed in a regular and uniform order. God does not act as a man acts by setting plans or purposes before himself and then proceeding to realize them, nor has he emotions or passions like men which move him now in this direction and now in that. Spinoza satirizes unsparingly the external teleology and anthropomorphism of his day which sought to explain the course of natural events by referring them to special ends and purposes on the part of God. For Spinoza, God is not transcendent, existing apart from nature, but nature itself as an active self-determining process (*natura naturans*) is God. The one infinite substance, or God, has an infinite number of attributes, but it is known to us solely through the two attributes of extension and thought. Thus every physical thing is a mode of extension, and every idea a mode of the attribute of thought. The physical and the psychical are not independent substances, as Descartes supposed, nor is there any interaction between them. The truth is, that physical things and thoughts are modes which express the nature of the one substance, but each side expresses this nature in terms of a different attribute. Yet though there is no interaction there is an exact correspondence between the modes of extension and the modes of thought: "the order and connection of ideas is the same as the order and connection of things." This is Spinoza's statement of the Parallelism (q.v.) of mind and body, a doctrine which he was the first to maintain. He develops this theory in some detail, defining the mind as the "idea of the body," and emphasizing the correlation between the perfection and development of the body and the effectiveness and sanity of the mind.

It is with the problem of man's place in nature—his relation to God or the total system of things, and the possibility of his freedom—that Spinoza is most directly concerned. Here he shows that the possibility of man's freedom depends upon his first recognizing that he is a part of nature, and that his mind, like everything else, is subject to uniform natural laws. Man forms no "kingdom within a kingdom"; it is not contingency or some strange power of free will which governs his mental experiences; but here as elsewhere all takes place according to law and necessity. "Nature's laws and ordinances whereby all things come to pass and change from one form to another are everywhere and always the same. There should, therefore, be one and the same method of understanding the nature of all things whatsoever, viz., through nature's universal laws and rules." Accordingly he

proceeds: "I shall consider human actions and desires in exactly the same manner as though I were concerned with lines, planes and solids." From this standpoint he gives a scientific account of the origin and nature of the emotions, showing how they necessarily arise from certain assignable causes, and how their intensity depends on definite natural conditions. The various emotions are all found to be compounds of the primary states, pleasure, pain and desire. But this reduction of the emotions to law is only a preliminary step in Spinoza's treatment. To attain freedom, it is first necessary to recognize the bondage of man, the fixed determination of the emotions through natural laws. But just as knowledge is power in regard to external nature, so we can free ourselves from the emotions by understanding their laws. The mind is, after all, something more than a series of passive states. Its essence consists in an effort to preserve its own being to promote its own good. And in carrying out this purpose it finds that nothing is so serviceable as knowledge. Through knowledge it is possible to free man from the bondage of the emotions. An emotion when understood becomes transformed and ceases to be a mere state of passivity. Moreover, when the conditions of an emotion are understood, it is possible to arrange and associate the various emotions in such a way as to strengthen and promote the occurrence of those that are desirable, and to weaken and repress those which are hurtful. The highest kind of knowledge for Spinoza is not scientific reason, but intuition, the direct insight that all things follow necessarily from the nature of God and hence form one system. To see all things, not as a series of events in time, but in their necessary logical relation to God, is what Spinoza calls viewing the world under the form of eternity (*sub specie aeternitatis*). And this highest knowledge gives rise to the intellectual love toward God (*amor intellectualis*) which is the highest good or blessedness for man. It is through the strength of this emotion, which is not a passion but the highest activity of mind, that the other emotions are more successfully governed and transformed. This intellectual love toward God enables the mind to renounce entirely all finite or personal desires, as well as all envy and jealousy. "He that loves God does not demand that God should love him in return"; he demands nothing for himself, but acquiesces completely in the order of the universe. Moreover, Spinoza argues that since this knowledge and the intellectual love to which it gives rise are eternal, the mind which experiences these must have something in it which is eternal and which cannot be destroyed with the body. Scholars, however, maintain that it is still doubtful whether Spinoza pronounces in favor of individual immortality. An interesting feature of Spinoza's philosophy is the close relation which he always recognizes between the individual and society. It is no merely individual good for which he was seeking but one which as "many others as possible" might share with him. In numerous passages he approached very near to the modern conception of the individual as standing in an organic relation to society.

For about a century after Spinoza's death

his philosophy was wholly neglected, and his name used by both orthodox and unorthodox writers in a depreciatory way as that of an utter atheist who deserved little attention. Lessing was the first thinker who knew and appreciated Spinoza, and a controversy after his death between Mendelssohn and Jacobi as to Lessing's real opinions did much to spread a knowledge of the system in Germany. Goethe was deeply influenced by Spinoza and helped to awaken interest in the Spinozistic philosophy. Thus, since the beginning of the 19th century, Spinoza's ideas have affected in important ways the development of modern thought. It was Novalis who called Spinoza "The God-intoxicated man."

Bibliography.—The standard edition of Spinoza's works is that edited by Van Vloten and Land (2 vols., 1882-83; also in a cheaper form, 3 vols., 1895). The chief works have been translated into English by R. H. M. Elwes (Bohn Library, 2 vols.). The 'Ethics' and the 'Improvement of the Understanding' are also translated by W. H. White and Miss A. Stirling (2d ed., 1899), and the 'Ethics' in part by George S. Fullerton in 'The Philosophy of Spinoza' (2d ed., 1894). The best general commentary in English is Sir F. Pollock's 'Spinoza: His Life and Philosophy' (2d ed., 1899). Consult also Caird, J., 'Spinoza' (Edinburgh, 1888); Joachim, H. H., 'A Study of the Ethics of Spinoza' (Oxford 1901); Duff, R. A., 'Spinoza's Political and Ethical Philosophy' (Glasgow 1903).

JAMES E. CREIGHTON,

Professor of Logic and Metaphysics, Cornell University.

SPIRACLES, the apertures on the sides of the body in insects, centipedes, spiders, etc., through which air is admitted to the breathing organs or tracheæ. See INSECTS.

SPIRÆA, a genus of deciduous shrubs of the order *Rosaceæ*. The species (about 50) are natives of the northern temperate zone; but, being widely popular in shrubberies, an enormous number of varieties have been produced, and the plants have been introduced into southern temperate countries, where some have escaped from cultivation. They are medium or small shrubs with usually little leaves and corymbs, panicles or umbels of white, pink or light crimson flowers, which appear either in profusion for a short time in spring or more sparsely and for a longer period during summer. The various species and varieties are adapted to a wide range of soils and situations, from swamp to rocky hillside and from the full glare of the sun to shade. Consult Baily, 'Cyclopedia of American Horticulture' (New York 1900-02).

SPIRAL, a curve, line or thing that winds about a centre, while also receding from it. The turns or whorls may be flat in one plane, or may rise spire-like, hence the name. Less accurately one that winds around a central axis, while advancing, as in a familiar form of coiled spring; properly this is helical. In geometry the term is confined to a curve in a plane that winds continuously around a centre with steadily increasing radius vector; also a single complete turn in such a continuous spiral. A so-called spiral that departs from a plane is the loxodrome. The mechanics of spirals have

proved of great interest in logarithms. See CURVES, HIGHER PLANE; SPRING.

SPIRE, a sharply-pointed, tapering roof, most commonly the roof of a tower, though a light structure often set at the crossing of the roof in a cruciform church is also called a spire (French, *flèche*), the term covering the lantern with upright sides from which the pointed roof swings. The term is hardly applied to a roof of which the slope is less than an angle of 60° with the horizon and even a slope of that acuteness makes a blunt spire.

Spires may be formed of wood and covered with wood or metal or even tiles, exactly like an ordinary roof of lower pitch, but the aim has always been to build the whole of stone and top it with a cross or a final of leafage or both.

The spire is associated with mediæval building in the west of Europe, and its greatest development is of the years 1180 to 1500 A.D. In later Gothic art the spire loses its character of roof in that its surfaces are occupied with open or pierced tracery, as in the German churches of Freiburg in Baden and Thann in Alsatia (Alsace), and the cathedral of Burgos in Spain. In the granite-building country of Brittany this decoration is common, though the openings are smaller and the spires look more massive. The latest development is that seen in Antwerp Cathedral and in Strassburg Cathedral. At Strassburg the roof lines have disappeared and the spire is a cage of sloping bars of stone which carry an indefinitely great number of pinnacles; and in Antwerp a series of vertically-walled lanterns are surrounded by bold pinnacles which are themselves spirelets of considerable size, the whole tapering to the cross. Other spires of the same 15th century and 16th century Gothic have pierced galleries or open stories of arched work alternating with the solid and roof-like slope of the spire. Such a one is the famous north tower of the Cathedral of Chartres.

The highest spires existing are those of Cologne Cathedral (modern from ancient design), 511 feet from pavement to top of cross; the Church of Saint Nicholas at Hamburg, 475 feet six inches; Strassburg Cathedral, 465 feet; Church of Saint Martin at Landshut in Lower Bavaria, 462 feet; the Church of Saint Stephen, Vienna, 450 feet; Antwerp Cathedral, 407 feet six inches; Salisbury Cathedral, 400 feet. Structures in metal are not considered here.

RUSSELL STURGIS.

SPIRES, spîrz (German SPEYER, spi'ër), Germany, in Bavaria, capital of the district of Pfalz, at the confluence of the Rhine and the Speierbach, 10 miles southwest of Mannheim. It is an important government town, ancient royal residence, religious centre of various denominations and the seat of the German Diet. The chief glory of the town is its cathedral (1030) begun by Conrad and completed by Henry IV (1061). It has been embellished by frescoes and statuary, and the ashes of eight German sovereigns repose within its walls. Other interesting buildings are the Retscher palace, the consistory, the gymnasium, a Roman Catholic seminary and other institutions, hospital, orphanage, a real-school and a museum containing German antiquities. The important industrial works include foundries, cotton mills, breweries; the manufacture of machinery, tobacco and leather goods. The Reformers here

first protested (1529) against existing Catholic dogmas and institutions. Pop. 21,856.

SPIRIT FRESCO. See PAINTING, TECHNIQUE OF.

SPIRIT OF LAWS, The (*L'Esprit des Lois*). "Montesquieu," says Professor Giddings, "converted social philosophy into descriptive social science." An eminent modern sociologist thus concisely summarizes the fundamental contribution of one of the most prominent participants in that general intellectual movement which brought about the transformation of social philosophy into the modern science of sociology. The work which rightfully entitled Montesquieu to this important distinction was 'The Spirit of Laws,' which appeared in 1748.

'The Spirit of Laws' has traditionally been regarded as primarily, if not entirely, a contribution to the literature of political theory and, more specifically, as the work which gave the doctrine of the "separation of powers" its vital impulse and made it both a persistent dogma in political science and a leading principle in modern constitutions. Viewed in its broadest aspects, however, this major work of Montesquieu was more than the instrument for the promulgation of a single dogma in political theory; it was even more than an extensive treatise on general political theory; it was, in fact, a most significant and influential contribution to the literature and methodology of general social science. 'The Spirit of Laws' was differentiated from the contemporary works on political theory not only by the profundity and scope of its inquiry, but also through the method by which it approached the problem of the analysis of the chief factors in social and political organizations. It was the first great inductive and objective analysis of social and political processes since Aristotle's 'Politics,' written some 2,000 years before. There had been plenty of semi-descriptive material in the works of earlier and contemporary writers, but this had been mainly concerned with scenes and episodes from biblical and classical mythology and history, in which the presentation of the exploits of Nimrod, Seth and Enoch and the heroes of Homer and Livy had been much more conspicuous than an analysis of contemporary societies. Montesquieu reflected the influence of the geographic discoveries of the two previous centuries by virtue of the fact that he turned his attention to the many and varied types of existing societies and sought his "men of nature" among living savages rather than among the mythical personages who had exhibited their characteristics in the period before the "fall of man." 'The Spirit of Laws,' then, was as truly the point of departure for modern descriptive sociology as was Hume's 'Treatise of Human Nature' for psychological sociology. By emphasizing the fact that wide observation must precede generalization, he gave a practical application in social science to the general methodological principles which had been advanced in natural science by Francis Bacon. This constitutes the enduring contribution of Montesquieu to the history of social science and political theory and it will remain unim-

paired long after his specific doctrines have become obsolete and forgotten.

Such is the general significance of the work of Montesquieu as set forth in 'The Spirit of Laws'; his specific contributions may now be summarized. Among the more important of these was his conception of the origin and nature of law. Comte, in describing the significance of 'The Spirit of Laws,' said on this point: "The great strength of this memorable work appears to me to lie in its tendency to regard political phenomena as subject to invariable laws like all other phenomena." Montesquieu's definition of law as "the necessary relations springing out of the nature of things" was truly epoch-making, being in all probability the first correct statement of what is now generally accepted as an accurate definition of a sociological law. From the different types of relationships there proceeded the various types of laws, as, for example, political law grows out of the relations of the governed and governing in any political community; and civil law out of the everyday relations between the individual citizens in the community. Laws, springing thus out of basic relationships, must be related to the particular circumstances of a given society and its environing conditions. Laws are, therefore, natural and beneficial just in proportion as this perfect adaptability between a law and its social environment is attained. Finally, all types of laws are closely inter-related and should be consistent in their totality. The highest achievement of human intelligence is to secure this consistency of all types of laws and to prevent the encroachment of any type upon the domain of another. The entirety of these relationships—of social groups and individuals giving rise to human laws; of laws to the social and physical environment, and of the different types of laws to each other, constitutes the spirit of laws and Montesquieu's main task was to trace in some detail the nature and results of these relationships.

Following the general premises laid down above, another highly significant proposition advanced by Montesquieu, in which he was thoroughly in accord with modern social theory, was that in which he relinquished the contemporary absolutism regarding social and political organization and maintained the then novel doctrine of the relativity of the excellence of institutions. The excellence and effectiveness of laws and of social and political institutions he held to be dependent not upon any intrinsic superiority, but upon their specific adaptability to the particular social environment in which they are found or in which they may be intended for application. Now the social environment, according to Montesquieu, is essentially determined by the historical conditions of the development of the particular society and by the surrounding physical environment. In accordance with this type of reasoning he endeavored to discover and indicate the relative excellence of the different forms of law, political organization and social institutions among the diverse peoples of the earth according to their relation to the various conditions of the physical environment and the resulting national of social and political phenomena, and he presented what was by far the most complete and accurate interpretation of social processes and political institutions in terms of environmental

influences that had been developed by any traits and customs. This led him into the most comprehensive inductive and descriptive study writer. His treatment of the significance of climatic conditions upon mankind was especially exhaustive and has had a wide influence. But while Montesquieu's studies along this line gave an added impetus to the development of that school of "environmentalists" which has been most notably represented by Ritter, Buckle, Ratzel, Semple and Huntington, his theories were by no means original. As Dedieu has recently shown in a most convincing manner, Montesquieu took over his environmental theories bodily from the English physician Arbuthnot's 'Essays on the Effects of Air on Human Bodies' and drew his descriptive material almost wholly from Chardin's 'Travels in Persia.'

While Montesquieu has received the respectful attention of sociological writers chiefly on account of his emphasis upon the element of descriptive analysis and his environmental theories, his past reputation and his present notoriety among political theorists has been founded upon his famous doctrine of the separation of governmental powers as the chief safeguard of political liberty. This theory, again, was not original as it was taken almost directly from Locke's differentiation of the powers of government into the legislative, executive and federative branches; but Montesquieu brought his analysis more into harmony with modern political terminology, and his treatment was so vigorous and elaborate that the doctrine has become inseparably connected with his name. Accepting this tripartite division of governmental powers as a logical and fundamental necessity, Montesquieu argued that each function must be exercised by a separate and independent organ if any guarantee of political liberty was to be secured by the citizens. This famous doctrine was deeply absorbed by the framers of the Constitution of the United States, and it was given a more important place in that document than any other single dogma of political science. Famous and influential as this theory may have been, however, it is now generally recognized to be historically inaccurate and practically unworkable. Montesquieu derived his dogma from a superficial study of the externals of the English Constitution, while, in reality, by 1748 the totality of governmental powers in England had become absorbed by the single branch of the Parliament and the Cabinet, viewed as a committee of the Parliament. Not only was it thus, in its origin and derivation, the result of a misinterpretation, but, as Professors Ford, Goodnow and Powell have so clearly pointed out, it has proved unworkable in practice: and most of the advances which the United States has made in effective national administration since 1787 been effected by gradually breaking away from the practical application of the doctrine of the separation and independence of governmental powers.

One more specific contribution made through the 'Spirit of Laws' should be mentioned and that is the calm and judicious criticism of the cruel, barbarous and irrational criminal procedure of the time and the moderate and enlightened suggestions offered as to the methods whereby it could be reformed. It was from the

treatment of this subject in the 'Persian Letters' and the 'Spirit of Laws' that Beccaria received his inspiration for his epoch-making work on 'Crimes and Punishments.' In attempting, by way of summary, to differentiate the elements of permanent value in Montesquieu's work from what is transitory or already antiquated or discredited, it seems safe to hold that he will be accorded a permanent and honorable place in the history of the development of social science and political theory on account of the vigor and priority of his insistence upon the doctrine of the relativity of the excellence of institutions according to their adaptability to the characteristics of a given population and upon the proposition that sociological and political generalizations must proceed from a wide observation of concrete facts and conditions and not from a priori assumptions of the deductive philosopher. These will ensure him the respectful consideration of the student of the history of social science long after his unfortunate insistence upon the doctrine of the separation of governmental powers has been forgiven if not forgotten. The standard edition of Montesquieu's works is that by E. Laboulaye (7 vols., Paris 1875-79). Nugent's translation of 'The Spirit of Laws' has acquired something of the reputation of a classic. The best analysis of the doctrines of Montesquieu in English is to be found in chapter XII of W. A. Dunning's 'History of Political Theories from Luther to Montesquieu.' More extended treatments are to be found in Janet's 'Histoire de la science politique' (Vol. II, pp. 322-399); in Franck's 'Réformateurs et publicistes de l'Europe' (Vol. III, pp. 133-283), and in Dedieu's 'Montesquieu et la tradition politique anglaise en France.' Montesquieu's contributions to history are analyzed and appraised by Fueter, 'Histoire de l'historiographie moderne' (pp. 475-478), and in Flint's 'History of the Philosophy of History' (pp. 262-280).

HARRY ELMER BARNES,

Professor of History, The New School for Social Research, New York City.

SPIRIT LEVEL, an instrument used by surveyors and others for determining a level or plane parallel to the horizon and also the relative heights of two or more stations. It consists of a glass tube nearly filled with alcohol, preferably colored. The remaining space in the tube is a bubble of air and this occupies a position exactly in the middle of the tube when the latter is perfectly horizontal. The tube is mounted on a wooden bar, which is laid on a beam or other object to be tested; or it is mounted on a telescope or theodolite and forms the means of bringing these instruments to a level, the slightest deviation from the horizontal position being indicated by the bubble rising toward the higher end of the tube. The spirit level quadrant is used for taking altitudes.

SPIRIT PLANT, called the Holy Ghost Flower, an orchidaceous plant (*Peristeria elata*) of Central America, known also as the *dove-plant*, from the resemblance of the united stamens and pistil of the flower to a dove hovering with expanded wings, somewhat like the conventional dove seen in artistic representations of the Holy Ghost. It has a spike of al-

most globose, sweet-scented flowers of a creamy white, dotted with lilac on the base of the lip.

SPIRITUAL CORPORATIONS, in the law of England, corporations, the members of which are "spiritual persons" or clergymen, incorporated for the furtherance of religion and perpetuation of the rights of the Church. The laws of the States of the American Union do not recognize any difference between ecclesiastical (or spiritual) and other corporations; the same statutes apply to both kinds of corporations.

SPIRITUAL EXERCISES (*Ejercicios Espirituales*). The Jesuits have occupied a prominent place in the intellectual and spiritual life of the world since their foundation nearly 400 years ago. Their founder, Saint Ignatius Loyola, as well as the Jesuits themselves have always attributed whatever of influence they had to the formation of their characters by the 'Spiritual Exercises.' This is a little volume which contains the result of Ignatius' own experiences in the spiritual life. The title given it by its author was 'Spiritual Exercises To Conquer Oneself and Regulate One's Life and to Avoid Coming to a Determination Through any Inordinate Affection.' He wrote it in Spanish, but made a translation into Latin, and it is this which is usually referred to as the original. The book is really a manual for four weeks of meditations on the significance of life and how it should be lived. The four weeks have been summed up briefly in the words (1) *deformata reformare*; (2) *reformata conformare*; (3) *conformata confirmare*; (4) *confirmata transformare*; that is (1) to reform what is deformed by sin; (2) to make what is thus reformed conform to the Divine model, Christ; (3) to strengthen what is thus conformed; (4) to transform by love the firmly made resolutions. The first week of the Exercises is called "the purgative way" because it dwells on cleansing from sin; the second and third are called "the illuminative way" because they are devoted to the intensive contemplation of the light cast upon life by the example of Christ's life; finally there is "the unitive way" by which intimate union with Christ is sought. So far from being a merely conventional spiritual book, the 'Spiritual Exercises' has been set beside the 'Imitation of Christ' by many competent critics. Janssen the German historian declared that "no other ascetic work may be compared to it." The French positivist, Lafitte, in a lecture delivered at the Collège de France, declared "These exercises are to my mind a real masterpiece of political and moral wisdom and merit careful study." It is not a book to read merely, but to live for the periods indicated. It is the basis of retreats for religious and seculars throughout the world, and serious non-Catholics often turn to it for direction in spiritual exercises. Consult Clare, 'The Science of the Spiritual Life According to the Spiritual Exercises' (New York 1896); Diertins, 'Historia Exercitiorum spiritualium' (Rome 1732); Roothaan, 'Exercitia Spiritualia' (Rome 1835); The author was General of the Jesuits and his notes are illuminating; Shipley, 'Spiritual Exercises' (London 1870); Bouhours, 'Life of Saint Ignatius' (trans. by John Dryden, London 1686).

JAMES J. WALSH, M.D.

SPIRITUALISM, the movement, based on belief in the genuine character of Spiritualistic phenomena, that originated in 1848, in the experiences of the Fox family of Hydesville, N. Y., and which within a few years spread over the United States and England and later over the civilized world. Also the philosophy or religion based on communication with spirits or discarnate human intelligence, through the process of mediumship. The Spiritualists had in the United States, in 1918, about 200 churches and a membership of about 600,000. Within recent years many distinguished people have declared their conviction that human beings not only continue to live after "death," so-called, but that communication with them is more or less common. Among such may be cited William E. Gladstone, A. J. Balfour, Oliver Lodge, William Crookes, Henri Bergson, Césaire Lombroso, Camille Flammarion, Schiaparelli, Conan Doyle, A. R. Wallace, William James, J. H. Hyslop, J. J. Thomson, Alfred Tennyson, Frederick Tennyson, John Ruskin and R. L. Stevenson. Many others might be added, but these are sufficient to show the dignity of the intelligences that accept Spiritualism as a fact. On the other hand, some hundreds of books have been published and innumerable magazine and newspaper articles printed, advertising and describing the frauds and humbugs of Spiritualism and many of these have come from men of high intelligence and culture, evidently wholly convinced that they were doing the world a service in exposing fraud. In this conflicting state of affairs it is necessary for an impartial statement to include all sides of the case, without effort to prejudice the reader.

History of the Movement.—In 1848 the home of J. D. Fox of Hydesville, Wayne County, N. Y., was the scene of "rappings" and various noises, accredited to spiritual agencies. The house was visited by a great many people, most of whom came away convinced that a supernatural agency was at work. Later the two daughters of this family, Kate and Margaret, moved to Rochester, where they became still more famous as the Fox sisters, being known by this name long after they married. These young women developed into what are now known as Spiritualist mediums, and produced or assisted in a variety of phenomena; went into trances and interviewed dead relatives for literally thousands of people and also brought messages from distinguished great men, in large numbers. Next appeared Andrew Jackson Davis, of Orange County, N. Y., who, when a very young man of moderate education, began to go into trances and received a great deal of scientific and philosophical information, which he put into books and lectures. His book 'Principles of Nature,' written while he was in his 'teens, passed through 34 editions. He was in great demand as a lecturer for many years and later started a publishing house in Boston to publish his own and other Spiritualistic books. Hudson Tuttle and Cora V. Richmond also developed as inspirational lecturers and writers, and their works are to be found in all large libraries. When only 17 Miss Richmond delivered remarkable addresses in a state of semi-trance, which it was admitted by all she was incompetent to produce by her own mentality. The movement spread into Eng-

land, two of the most active being D. D. Home, a remarkable medium, and W. Stainton Moses, an Episcopal clergyman and Oxonian. These two lights startled England for several years. At Home's seances he used to pick up live coals from the fire by the handful and carry them around without being burned. Many of his pupils were trained to do the same thing, and he was even known to wash his face in the flames unharmed. And these things were testified to by numerous and intelligent witnesses. Moses started a publication in London, *Light*, about 1872, and working with his friend, Mrs. Speer, gave many marvelous exhibitions, developing cabinet tricks, automatic writing, slate-writing, table-tipping, etc. Slade, Bishop and a host of others gave similar exhibitions in the United States, while in France, Cahagnat, Reisenbuch and DuPotet made investigations and gave seances. The *Banner of Light* was published in Boston as the principal American organ of the cult and Spiritualist societies sprang up everywhere and the work developed into a religion, which at its height had nearly 2,000 churches or assemblies in America.

Then came a period of investigation and exposure. Mediumship and trance exhibitions, slate-writing, etc., proved so profitable that many sleight-of-hand performers, legerdemain artists and clever people engaged in it for profit, and it seemed impossible to distinguish the genuine from the impositions. There was so much discussion and dispute that in 1882 the Psychical Research Society was formed in London, and a few years later an American branch was organized. A large number of distinguished scientific men participated in this work, which many thought would result in demonstrating that Spiritualism was humbug and fraud from beginning to end. The American branch assisted the University of Pennsylvania in forming the Seybert Commission to investigate the phenomena of Spiritualism and Mediumship, and they promptly exposed a number of fraudulent mediums and their work, presented a 'Report' and dissolved. This was far from satisfactory, as it simply showed that a number of imitators of Spiritualist methods had hoaxed a large number of people. It left unsolved the question whether others were not genuine and whether there were not definite natural laws underlying the phenomena. So the Psychical Research Society continued its work and has now been active for more than 35 years and published voluminous reports or proceedings. Several of its prominent members have committed themselves to a definite conviction as to the truth of many of the phenomena and the genuineness of communications with intelligences called dead, but living on the higher planes. Their most exhaustive experiments were made with Eusapia Paladino and Leonora Piper, and for particulars of their work the reader is referred to PSYCHICAL RESEARCH in this Encyclopedia.

Mediumship and Its Methods.—Spiritualism is based on mediumship, or the use of a human being as a means of communication between discarnate intelligences (or dead people) and living persons. These mediums are usually persons of a nervous temperament, and they always must be passive to develop what is called the "power," but which might be better de-

scribed as the ability to interpret by submission of the will and voluntary senses. It is a subjective psychic process, and very wearing and trying upon the nervous system of the medium, and it has been contended that the disposition of mediums to impose upon the public was largely due to the fact that the work so exhausted them that they were unable to keep up with the demands of their sitters, and so "faked" interviews with the dead, to give them satisfaction. Impressional or inspirational mediums are those who do not go into a full trance, but are quite conscious of their surroundings, and who, when under this slight control, make addresses or write that which is impressed on their minds from the "other side" of life. This has been done so frequently, and such wise and learned utterances have at times come so fluently from mediums of moderate education, that the fact of their being more or less inspired by intelligences of greater ability than they themselves possess, has been widely admitted. The automatic writing form of mediumship is akin to this. The medium takes a pen or pencil and waits until some influence seizes his or her hand, and writing proceeds. The composition may be good, bad or indifferent. But since such a reliable man of world-wide fame as William T. Stead, in his 'Letters from Julia,' admits his hand was controlled and that the letters came from another intelligence; and so gifted an authoress as Elsa Barker has given us 'Letters of a Living Dead Man,' and the son of that dead man has recognized his father from the information, and some hundreds of other really valuable books have been produced in this way, the public is becoming less skeptical. The planchette and ouija board furnish another means of mediumship, the method being described under those terms. Trance mediumship is of several varieties; its leading characteristic is that the medium goes into an artificial sleep, similar to that into which the subject of a hypnotist is thrown. In fact all the conditions of hypnotism and trance mediumship appear to be identical except that the control in one case is a discarnate spirit and in the other a living hypnotist. This phase of the subject is very fully covered in F. Huntley's 'The Great Psychological Crime.' (See also HYPNOTISM in this Encyclopedia). The medium in a trance usually informs the sitters around that a certain individual is present, and the sitters are privileged to ask questions which the medium will answer for the spirit. The evidence that such testimony is not faked is that in a vast number of instances facts have been told of which the medium could have known nothing, and mediums have been known to speak in languages of which they were ignorant; and in many other ways the testimony has been held to transcend the ability of the medium to manufacture. Materializing mediums are rare, and this phase of mediumship has been most questioned; still there are so many instances well attested that it is hard to discredit them. A state of darkness or near-darkness is insisted on, and portions of human bodies, or an entire individual will be materialized and presented to the view of the audience, sometimes walking among them, and touching some of them, as well as engaging in more or less conversation.

It has been explained that this is accomplished by the medium's control, who draws upon the medium and the sitters for magnetism, and a certain amount of material matter, and builds this about a spirit form so that such spirit form is rendered visible. For the reality or non-reality of this phenomena the reader is referred to the bibliography at the close of this article. The subject is so disputed, and so difficult of proof, that it cannot be discussed at length here with profit. In addition to the foregoing, there are mediums who have practised a variety of cabinet tricks, as of speaking through trumpets, playing musical instruments, etc., while securely tied within a dark cabinet on the stage, the instrument being in full view of the audience and seemingly sounded without human agency. There is also a form of mediumship called "table tipping" which was very popular in England in the early days of the Spiritualist movement. Articles of furniture would be made to move about with no visible person or attachment. This seems to have been a form of levitation and this is fully discussed under that word.

Theories, Opinions and Beliefs.—Spiritualism is regarded from four different viewpoints by as many classes of observers. First, are those who are easily convinced of the reality of the communications with the so-called dead, who consider practically all mediums honest, to whom the philosophy has become a religion, and who derive a great deal of comfort from attending seances and meetings and getting messages mostly to the effect that their loved ones are well and happy. These are open and avowed Spiritualists, who resent any imputation as to the accuracy of the phenomena. Second, come those who believe the phenomena are produced wholly by trickery, legerdemain and magic, and constitute a great psychic fraud on the public. As a sub-class to these are a few who believe that "if there is anything in it, it must be the work of the devil or his subordinates." Third, are those who admit the genuineness of the phenomena (when not faked), but who contend that such communications only put sitters in touch with the lowest and least desirable class of spirits, with the ignorant, immoral and undeveloped spirits, this being why so many American Indian spirits appear. Emblematic of this class is Ruskin, who is quoted as saying that "Having learned through Spiritualism that there is another life, I have no farther use for it." Fourth, comes those who hold that the phenomena so widely exhibited is sometimes produced by trickery and sometimes by telepathic suggestion, by clairvoyance, telepathy and natural powers not wholly understood. Some of this class, like Sir Oliver Lodge (q.v.), have come out openly and admit their conviction of the absolute proof of intelligent communication with disembodied spirits; and others, like the late William James (q.v.), are inclined to think that the phenomena, which they admit, may be largely the reflex action of their own minds or the minds of others on the earth plane. It is this fourth class who largely constitute the members and followers of the Society for Psychical Research. That deep thinker and explainer of Darwin's theories of Evolution, Alfred Russel Wallace, said in Chambers' Encyclopædia, "Spiritualism has grown and

spread continually till, in spite of ridicule, misrepresentation and persecution, it has gained converts in every civilized portion of the globe." Sir Oliver Lodge has written: "I tell you with all the strength and conviction I can utter that we do persist, that people over there still take an interest in what is going on here; that they still help us and know far more about things than we do and are able from time to time to communicate with us."

Conclusions.—The conclusions of the higher intelligences who have expressed themselves as being convinced of the reality of Spiritualism may be summed up as follows: Through mediumship is proved the continuity of life beyond the grave; it is no longer a religious dogma but a living fact. Spiritual intelligences are as anxious to communicate with us as we with them, but the lower and grosser intelligence seem to be the nearest to us, and most likely to be heard from in communication, and they like to impersonate great individuals and personal deceased friends of those present. This is held to account for much of the "information" that comes through, and is valueless. For many years the *Banner of Light*, published in Boston, was the leading organ of this cult. In common with other Spiritualist papers it has disappeared. They have apparently given way to Psychological publications and New Thought periodicals. While the great public includes a vast number who are virtually Spiritualists, they are less and less known by that name, but are affiliated with New Thought, Mental Science, Theosophy, Oriental cults, Psychical Research and other modern movements.

Spiritualistic teaching is largely in accord with the writings in the Bible. The "familiar spirits" were very much like some modern ones that come to mediums; the witch of Endor, the ghost seen by Balaam, the experiences of many of the prophets and saints are paralleled in Spiritualism. Seers of all ages have testified to various things about the future life that are in accord with what comes to us through the séance room. Emmanuel Swedenborg (q.v.), one of the most modern seers, has told in many volumes of his experiences in the heaven world, which he was able to see and visit without a medium. And this seems to be the distinction between a seer and a medium: the former sees clairvoyantly with his own eyes; the latter goes to sleep and takes the word of some intelligence on the spiritual plane, which may or may not represent truth.

National Spiritualists' Association.—This was organized 28 Sept. 1893 and incorporated in the following November at Washington, D. C. It comprises about 1,000 active working societies and 22 State associations; there are also 32 camp meeting associations and perhaps 900 irregular unorganized local societies and meetings of Spiritualists. They maintain an academy equivalent to a seminary and include 200 churches with a membership of 600,000. There are believed to be about 1,500,000 others attendant on their gatherings or sympathetic with their work. Their secretary states that there are about 1,500 public mediums in the country, and a much larger number of private mediums. They have 500 ordained ministers and \$7,500,000 worth of church property. Their headquarters are at 600 Pennsylvania avenue, Washington, D. C.

See HYPNOTISM; MAGIC; PSYCHICAL RESEARCH; PSYCHOLOGY.

SPIROMETER, a contrivance for determining the capacity of the human lungs. The instrument most commonly employed consists of an inverted chamber submerged in a water-bath like a miniature gas-holder. The breath is conducted by a flexible pipe and internal tube, so as to collect in the chamber, which rises in the water and is fitted with an index marking the number of cubic inches of air expired after a forced inspiration.

SPIRULA, a genus of diminutive cuttlefishes representing the family *Spirulidae*, which is distinguished by the possession of an internal chambered shell of nacreous structure and discoidal form, the whorls of the shell being separate, and the siphon piercing the septa on their ventral surfaces. *S. peronii* is a species which inhabits the open ocean, and its shells are occasionally cast ashore. See CEPHALOPODA.

SPITHEAD, England, a roadstead which separates the northern coast of the Isle of Wight from the mainland near the entrance to Portsmouth Harbor (q.v.). It is much frequented by the English fleet and protected by strong forts, and extends for about two miles along the southwest side of Spit Sand. It is so safe that it received the title of the "King's bedchamber." In 1797 it was a scene of a determined mutiny, the sailors striking for better pay, which they obtained.

SPITTA, Julius August Philipp, German musical historian: b. Wechold, Hanover, 27 Dec. 1841; d. Berlin, 13 April 1894. He was educated at the University of Göttingen. He engaged in teaching, meantime making a study of the history of music and musicians. The appearance of the first volume of his life of Bach (2 vols., 1873-82) brought him immediate recognition, and in 1875 he was appointed professor of musical history at the University of Berlin, and perpetual secretary to the Academy

of Arts there. He was also connected with the High School of Music from 1875, and from 1882 was a permanent director. He wrote the biographies of Bach and Schumann for the 'Musikalische Vorträge,' as well as the article on Spontini for that work. He was co-editor of *Vierteljahrsschrift für Musikwissenschaft*; edited the organ works of Buxtehude (2 vols., 1875-76); and the complete edition of the works of Heinrich Schütz.

SPITTA, Karl Johann Phillip, German hymnist: b. Hanover, 1801; d. Burgdorf, 1859. After completing studies at Göttingen University, he taught from 1824 to 1828 at Lüne, where he composed the hymns which brought him into prominence. He served as pastor in several localities and became superintending clergyman at Burgdorf in 1859, a short time before his death. His hymns of perfect lyric form and purity of style are marked by spiritual elevation and a wealth of thought and sentiment embodied in fresh, vigorous language. They came into general use and retain a high position in the hymnology of the period. They appear in 'Nachgelassene geistliche Lieder' (1861 et seq.); in 'Psalter und Harfe' (1833; rev. ed. with bibliography, 1890; Jubilee ed. 1901). Consult Munkel, 'Phillip Spitta' (Leipzig 1861); Majer, 'id.' (2d ed., (Bremen 1891).

SPITS. See SHORE LINE.

SPITTELER, Carl, poet: b. Liestal near Basel, Switzerland, 24 April 1845. His father was an official of the government, being Federal Secretary of the Treasury from 1849-56. Young Spitteler attended the gymnasium at Basel, being fortunate in having among his teachers such men as Wilhelm Wackernagel, the great philologist, and Jakob Burckhardt, the author of the famous work on the Italian Renaissance. Later he studied at the universities of Basel, Zürich and Heidelberg. He began with jurisprudence and afterward changed to theology, but when a position as pastor was offered him, he felt that he must decline it. He had begun to realize his mission as an epic poet and therefore refused to work in the field for which he had prepared himself. His first work, 'Prometheus und Epimetheus' appeared in 1880-81. It is an allegory which symbolizes the joys and sorrows of an exalted soul striving to attain an ideal, although the loyalty to this ideal is paid for by a life full of misery. The style reminds one of Nietzsche's 'Zarathustra,' but Spitteler was not influenced by Nietzsche, as that is chronologically impossible. Rather the reverse is true, although Nietzsche never acknowledged his indebtedness to Spitteler. The two works in a way complement each other. In Nietzsche we have direct didactic statement, while in Spitteler a higher phase, the symbolical, is predominant. From 1870 to 1879 he spent in Russia as a private tutor and later he served as teacher in Neuenstadt not far from Berne. In 1882 he published his 'Extramundana,' a collection of poems. He gave up teaching in 1885 and devoted himself to a journalistic career in Basel. Now his works began to come in rapid succession. In 1891 there appeared 'Friedli, der Kalderi,' a collection of short stories, in which Spitteler, as he himself says, depicted Russian realism. In 1898 'Conrad der Leutnant' was published; 'Literarische Gleichnisse' had appeared in 1892, and 'Balladen' in 1896.

His most important production, 'Der Olympische Frühling,' appeared 1900-03 and was revised in 1910. It is an epic poem of the heroic type in which Spitteler has given us his interpretation of life. The ancient mythology is not used as a setting but as an appeal to the imagination. He tells of the doings of gods and men in an elevated style and by implication he impresses upon us his ideas and ideals.

Gottfried Keller, the realist, had some difficulty in understanding the allegorical works of Spitteler and his admirers have been few up to recent times. Now a better appreciation of his works seems to be coming. Consult Boesche, 'Life and Works of Carl Spitteler' (in 'The German Classics,' Vol. XIV, New York, 1914); Biese, 'Deutsche Literaturgeschichte,' Vol. III.

WILLIAM F. HAUHART,
Assistant Professor of German, University of Michigan.

SPITZ, or **POMERANIAN DOG**, a small sheep-dog, originally of the Baltic provinces of Germany, which is about the size of the spaniel, with a sharp-pointed face and an abundant white coat sometimes of great beauty. Other colors are known, including black. It was once comparatively common in the United States. See Dog.

SPITZBERGEN, spīts-bér'gën, a group of islands in the Arctic Ocean, between Barents Sea on the east and Greenland Sea on the west, about 650 miles north of the North Cape in Norway. They lie between the parallels 76° 30' and 80° 30' N., and are about 450 miles east of Northeast Foreland in Greenland and 200 miles west of Franz Josef Land. The archipelago comprises three large islands and a large number of smaller ones. The largest island is West Spitzbergen, which has an irregular triangular form with the apex pointing south. Its coast is indented by many fiords, of which the two largest are Ice Fiord on the west coast, running north and northeast, and Wijde Bay, penetrating southward from the north coast. The northern branch of Ice Fiord almost meets the head of Wijde Bay. The narrow Foreland Sound separates the smaller island of Prince Charles Foreland from part of the west coast of West Spitzbergen. To the northeast, separated from the main island of West Spitzbergen by Hinlopen Strait, lies the second largest island, North-East Land. Edge and Barents islands lie on the southeast side of the groups. Of the smaller islands, Danes Island, off the northwest coast of West Spitzbergen, is notable as the place from which Andrée set out on his fatal balloon voyage to the North Pole. At the extreme north is a cluster of small islands known as the Seven Islands. The total area of the archipelago is about 27,000 square miles, of which West Spitzbergen represents about 15,000. West Spitzbergen is in the main covered with great accumulations of ice, except along the west shore of Wijde Bay, where there is a relatively fertile area. The middle of the island, west of the main watershed, is described as a region of boggy valleys, fertile slopes and mountain ridges, or the remains of a high plateau. The highest measured peak of the island is Horn Sound Tind in the south, fully 4,500 feet above sea-level. Large glaciers are found throughout the whole group, but

especially on the eastern coasts. The average limit of solid drift ice skirts the northern edge of the archipelago. The ocean bed around the islands is shallow. Geologically the backbone of the island consists of granite, with gneiss and other archaic rocks, but Carboniferous, Triassic, Jurassic, Miocene and even more recent formations are also well represented. During Miocene times Spitzbergen had a luxuriant flora, and there was also a postglacial period of genial climate favorable to the development of a varied phanerogamic flora. The proximity of the Gulf Stream renders the climate, especially on the west coasts, less severe than that of other places in the same latitude. For four months in winter the sun is below the horizon, and for an equal period in summer always above it. The most characteristic plants of the archipelago are mosses and lichens. Rather more than 100 species of phanerogams, however, have been collected on the islands. The grasses form nearly a quarter of these, and next to them in number of species are the cruciferous plants. The larger forms of animal life are foxes, bears and reindeer, in pursuit of which, as well as the walruses and seals abounding along the coasts, the islands are frequently visited by the Norwegians and Russians. Sea-fowl are at times so numerous that they literally hide the rocks and darken the air. The minerals include beautiful marble and good coal. The group is said to have been discovered (1553) by Willoughby, but the islands were known to the Russians before that time. They were again discovered in 1596 by the Dutch navigator Barents. To the latter navigator the islands owe their name (in Dutch spelling, Spitsbergen), signifying "peaked mountains." The coasts of the chief islands have been explored by many expeditions since that time, and during the 19th century the islands were used as a base for expeditions toward the North Pole. The interior was hardly known till the explorations in 1896-97 of Sir W. Martin Conway, who was the first to cross West Spitzbergen from west to east. There are no settled inhabitants, but explorers and others have often passed one or more winters in the archipelago. In the days of the Spitzbergen whale fishery there was a thriving Dutch village called Smeerenberg on a small island to the northwest of West Spitzbergen. Tourist steamers sometimes sail to Spitzbergen during the summer months. A tourist hotel was built in 1896 at the entrance to Advent Bay, a branch of Ice Fiord.

SPITZKA, Edward Charles, American neurologist: b. New York, 10 Nov. 1852; d. 1914. He was graduated from the College of the City of New York and subsequently (1873) from the medical department of the University of New York, and studied later at the medical schools of Leipzig and Vienna, becoming in the latter institution a laboratory assistant in embryology and histology. On his return to New York he made the nervous system his specialty, and gained national reputation as expert in insanity in the trial of the assassin Guiteau. He is the discoverer of the inter-optic lobes of the lower brain. He was vice-president of the neurology section at the International Medical Congress of 1887, and honorary president of the Pan-American Medical Congress in 1893. He was editor of the *American*

Journal of Neurology (1881-84), and has published a 'Treatise on Insanity,' etc.

SPIVAK, Charles D., American physician: b. Kremenshtug, Russia, 25 Dec. 1861. Leaving Russia in 1882, on account of his political views he came to this country and worked as day laborer in New York, as a mill hand in Maine, and as a farmer in New Jersey, until he was enabled to graduate from the Jefferson Medical College, Philadelphia, in 1890, spending some time at the Berlin University (1891-92). In 1894-95 he was chief of clinic, gastro-intestinal diseases, at the Philadelphia Polyclinic. Settling in Denver, Colo., he became lecturer on diseases of the gastro-intestinal tract, Denver School of Medicine (1896-1900), and professor of anatomy at same college (1897-98).

SPLEEN, a vascular abdominal organ which, in man at least, is now generally regarded by physiologists as forming one of the ductless glands, and which is accordingly classed with the thyroid gland, thymus, and suprarenal capsules. All vertebrates—with the exception of the lancelet, and probably the lampreys, lepidosirens (or mudfishes), and the ceratodus or barramunda—possess a spleen, which is absent from the sub-kingdom in certain aberrant fishes only. In man, the spleen lies in the upper part of the abdomen, and is situated in the left hypochondriac region, contiguous to the cardiac or gullet end of the stomach. Its outer surface is smooth, and lies in contact with the under surface of the diaphragm or midriff, this latter muscle separating the spleen from the 9th, 10th and 11th ribs of the left side. Externally the spleen is covered by the peritoneum, and is connected with the stomach by the omentum, known as the gastrosplenic band. Its internal aspect is concave, and is divided by a longitudinal groove or fissure named the hilum. The blood-vessels and nerves of the spleen enter and leave the organ by the hilum. Inferiorly the internal surface of the spleen is in contact with the pancreas (q.v.) or sweetbread, and posteriorly with the suprarenal capsule of the left kidney. The upper end is of rounded conformation, and is thick; while the lower extremity is pointed, and is in contact with the colon (q.v.). A suspensory ligament or special fold of peritoneum attaches the spleen to the under surface of the midriff. The size of the spleen appears to vary much. Its average size in the healthy adult is about five inches in length, by three or four inches broad, and one to one and one-half inches in thickness. Its average weight is seven ounces.

The spleen is invested by an outer serous membrane formed by the peritoneal layers. It covers the entire surface. Below the serous coat is a second investment of fibrous nature. This is of elastic structure, and forms the framework or supporting fibres of the internal structure. The essential spleen matter is called spleen pulp. It is of a dark brownish-red color, and when microscopically viewed is seen to be composed of colored parts, consisting of red blood corpuscles and other cells of colored nature; while other bodies of deep-red, yellow, or black hue, existing singly or aggregated together, may be seen amid the spleen pulp. The colorless elements seen in the spleen-structure are granular matters, free nuclei of cells, as well as nucleated cells or vesicles. The colorless ele-

ments form about two-thirds of the pulp and are of the same nature as the round white cells of lymphatic glands (q.v.). They are also similar to white blood-corpuscles. When the spleen is cut through, as in a vertical section, a number of opaque bodies of small size, masses of round cells, are seen to be scattered throughout its substance. They are the Malpighian or splenic corpuscles, which have intimate relations with the veins of the spleen, and resemble lymph-corpuscles (see LYMPH) in form. The splenic artery, supplying the organ with blood, is of large calibre, and pursues a remarkably tortuous course within the spleen. The veins of the spleen, like the splenic artery, are of large relative size, and they unite to form a large (splenic) vein, which pours its fluid into the portal vein. The nerves of the organ are derived from the right and left semilunar ganglia, and form the right pneumogastric nerve.

The purpose and functions of the spleen have been the subject of much speculation; but in modern research has shown that in all probability the spleen is the seat of the change and elaboration of the red blood-corpuscles, which form such characteristic elements in vertebrate blood. It is thus to be regarded as a blood-gland, or kind of lymphatic gland. The spleen may be removed or extirpated, both from man and lower animals, without any apparent bad consequences. This is explicable on the ground that other glands (thyroid, thymus, or even the ordinary lymphatics) may assume the functions of the absent spleen.

Of the diseases to which the spleen is liable inflammation and enlargement are the most common. Inflammation (splenitis) may result in splenic abscess and gangrene; while the organ may be affected by various forms of tubercular and syphilitic disease, and is liable to be ruptured by violence—as from a direct kick or blow. Enlargement (known as ague-cake) results from chronic ague or intermittent fever, and may sometimes be met with in pregnant women, and in leucæmia (q.v.). See **INTESTINE**.

SPLEENWORT. See **ASPLENIUM**.

SPLICE. See **KNOTTING** and **SPLICING**.

SPLINT, in *surgery*, a thin piece of wood or other material, used to hold or confine a broken bone when set, or to maintain any part of the body in a fixed position. The original wooden splint is falling into disuse, modern surgeons preferring to build up something more easily molded to a desired shape. A plaster-of paris splint is made by charging a bandage of muslin or other open material with plaster of paris, and washing over each layer with water. The plaster hardens rapidly. Metal, wire, gutta percha and papier maché have also been employed. Often it is found advantageous to build up a plaster splint and stiffen it on a backbone of wood or metal.

SPLINT, in *veterinary surgery*, a bony enlargement on a horse's leg, between the knee and fetlock. It usually appears on the inside of one or both forelegs, frequently situated between the large and small cannon bones, is due to concussion, and most common in young horses that have been driven rapidly along hard roads before their bones are consolidated. When

of recent and rapid growth the splint is hot and tender and causes lameness. A piece of spongio-piline saturated with cold water should be applied to the splint, kept in position with a light linen bandage, and wetted with cold water or refrigerant mixture every hour. Perfect rest must be enjoined for 10 days or a fortnight. When the limb is cool and free from tenderness, the swelling, which will still remain, may be greatly reduced by some stimulating applications, such as the ointment of the red iodide of mercury, the common fly blister, or the firing iron.

SPLITAIL, a Californian chub (*Pogonichtys macrolepidotus*), dun-colored with silvery sides and the tail divided into two lobes, of which the upper is much the longer; length, 12 inches. It is common in all the lowland streams of central California.

SPLÜGEN, Switzerland, in the Alps bordering the Italian frontier, is a lofty mountain 9,350 feet high, with a pass connecting the Rhine Valley of the Grisons, with the valleys of Lombardy. The pass, though known to the Romans, was of a dangerous character, because of frequent heavy avalanches. A French army in 1800, traversing the old path, lost a great number of men and horses overwhelmed by avalanches. The modern pass, completed in 1823 by the Austrian government, contains several galleries of massive masonry as a protection against the descent of avalanches. It rises 6,940 feet above sea-level, and is a bold piece of Alpine engineering, rendering the route advantageous for automobile tourists fond of mountain travel. There is a small inn at a high point for the refuge of travelers, and a hotel at Monte Spluga. The scenery comprising deep cascades, sharp rocks, wild ravines and snowy peaks, presents a variety of magnificent views.

SPODUMENE, spōd'ū-mēn, a mineral occurring generally in monoclinic crystals often of great size. It has a well-developed cleavage, most perfect parallel to the orthodiagonal axis, and to the prism planes. It is not unlike feldspar in appearance, but may be distinguished from that mineral by its higher specific gravity (3.13 to 3.19), and its more pearly lustre. Its hardness is 6.5 to 7 of the scale, and its color grayish-green, passing into greenish-white and grayish-white, rarely faint-reddish. Its composition is: Silica 64.2; alumina 29.4; lithia 6.4. In eastern United States it is found at Windham, Me.; Winchester, N. H.; Goshen, Chesterfield and Norwich, Mass., and Brookfield, Conn. Very large crystals of the mineral are found in pegmatite dikes in the Black Hills, South Dakota. It also occurs in Sweden, in the Tyrol, and in Scotland. The mineral is valuable as a source of lithium, and a very transparent lilac-colored variety is used as a gem, under the name KUNZITE.

SPOFFORD, spōf'ōrd, Ainsworth Rand, American librarian: b. Gilmanton, N. H., 12 Sept. 1825; d. 11 Aug. 1908. He received a classical education from private tutors, engaged as a bookseller and publisher in Cincinnati, and in 1859-61 was associate editor of the Cincinnati *Daily Commercial*. He was first assistant librarian of Congress in 1861-64, librarian-in-chief in 1864-97, and chief assistant librarian till his death. He edited Catalogues of the

Congressional Library; 'Annual American Almanac' (1878-89); was associate editor of 'Library of Choice Literature' (10 vols.); 'Library of Historic Characters and Famous Events' (10 vols.); 'Library of Wit and Humor' (5 vols.); and has written 'Massachusetts in the American Revolution' (1895); 'A Book for All Readers' (1900), etc.

SPOFFORD, Harriet Elizabeth Prescott, American poet and writer of fiction: b. Calais, Me., 3 April 1835. She was graduated from the Pinkerton Academy in Derry, N. H., in 1852 and was married to R. S. Spofford in 1865. She was one of the earliest contributors to *The Atlantic Monthly*, her story 'The Amber Gods,' attracting the attention of discriminating readers as much for the tropical luxuriance of its style as for the theme. Her earlier work in both verse and prose is in every case marked by originality and distinction of style, but her later work, while not without charm, is more conventional and informing. Among her publications are 'Sir Rohan's Ghost' (1859); 'The Amber Gods, and Other Stories' (1863); 'Azarian' (1864); 'New England Legends' (1871); 'Hester Stanley and Saint Marks' (1883); 'A Scarlet Poppy' (1895); 'In Titian's Garden,' verse (1896); 'Old Washington' (1906); 'The Making of a Fortune' (1911).

SPOHR, spōr, Ludwig, German composer: b. Brunswick, 5 April 1784; d. Cassel, 22 Oct. 1859. He studied music, and at an early age acquired a great reputation as a performer on the violin. About 1805 he was appointed conductor of the court concerts at Gotha, and became afterward musical director of the Theatre an der Wien, Vienna, for which he wrote some of his finest dramatic works. He became chapel-master at Frankfort, 1817-19, and at the electoral court of Hesse-Cassel in 1822, and continued in that office till near the end of his days. Spohr was the composer of violin music, consisting of solos, concertos and chamber-pieces, and his performance on that instrument was characterized by breadth and vigor of tone. He is also the author of 'Faust' (1818); 'Jessonda' (1823); 'Zemire und Azor' (1819), and other operas, which occupy a high rank among musical compositions. His oratorios, 'The Last Judgment' (1826); ('Die letzten Dinge'), 'The Fall of Babylon' (produced first at a Norwich musical festival), and 'Calvary' (1835), ('Des Heilands letzte Stunden'). His last opera was 'Die Kreuzfahrer,' produced in 1845. His finest symphony was 'Die Weihe der Tone' (1832).

SPOILS SYSTEM. See CIVIL SERVICE REFORM.

SPOKAN. See SALISHAN INDIANS.

SPOKANE, Wash., city, county-seat of Spokane County, and the commercial and financial centre of the territory known as the Inland Empire, comprising eastern Washington, northern Idaho and western Montana. Spokane to the Indian tribe of that name meant "Children of the Sun." The place was originally called Spokane Falls, so named from the series of cascades in which the Spokane River falls through the heart of the city. Five transcontinental railroads operate into Spokane over their own tracks—the Northern Pacific, the Great Northern, the Chicago, Milwaukee and Saint Paul, the Canadian Pacific and the Ore-

gon-Washington or Union Pacific. Two others, the Burlington and the Northwestern, operate under traffic agreements. All have branch lines radiating into the corners of the Empire. The heart of the city is bisected by the Spokane River, having a series of abrupt falls making possible the development of 400,000 horse power of electrical energy. Only 172,000 horse-power has been developed up to the present for the operation of Spokane street cars and the illumination of the city and to provide power for the factories of Spokane and the surrounding country. This power also is transmitted 100 miles east to the Cœur d'Alene mining district. The city of Spokane, which in 1900 had only 36,000 inhabitants, had in 1910 a population of 104,402, according to federal census.

Industries.—Spokane's factory output is valued at \$50,000,000 per year, and 12,000 are employed in manufacturing. Some of the different industrial establishments are lumber mills, manufacturing different kinds of lumber products, sewer and water pipe works, flour mills, flour mill machinery works, brick and terra cotta works, foundries, vinegar and pickle works, machine shops, iron works, cereal food plant, pottery, mattress and furniture factories. Other manufactures are jewelry, tobacco products, gloves, clothing, brooms, trunks, wooden and tin ware, dairy products, packed and canned meats. A large part of the industrial prosperity is owing to the mines in the vicinity, the great agricultural and horticultural resources of the surrounding territory, extensive stock-raising, and to the vast water power which offers special inducements to manufacturers. This power is made available by the generation of electricity. Spokane is also the centre of a rich lumbering region. The city is surrounded on the north, east and south by the greatest area of white pine timber forests in the United States. The city has grain elevators, an electric light plant, an artificial gas plant and large lumber yards.

Commerce and Transportation.—Spokane is the commercial as well as the industrial centre of eastern Washington, northern Idaho and western Montana. Spokane ships to the markets of the world the fine wheat from the interior basin of the Columbia River, the vegetables, deciduous fruits, berries and the products in general from a region of fertile soil, and the semi-arid districts of the Spokane, Yakima and Wenatchee valleys, made productive by irrigation. Crop failures in this region, popularly known as the "Inland Empire," are unknown. The wealth production from the farms, orchards, mines, forests and ranges of the Spokane country in a recent year amounted to \$217,158,000, as follows: Grain yield, \$93,000,000; mineral output, \$41,158,000; livestock and poultry, \$27,500,000; lumber, \$14,500,000; farm and garden products, \$17,000,000; apples and other fruits, \$11,000,000; dairy products, \$13,000,000; total, \$217,158,000.

Public Interests.—Spokane is finely situated in the Spokane River Valley. In summer the winds from the Cascades and Rockies temper the heat, while the breezes from the Japan current of the Pacific Ocean make extreme cold unknown here. In the 35 years that the United States Weather Bureau has been here, there has not been an instance of loss of life from extreme heat or cold or other climatic conditions,

such as heavy winds. Spokane leads all cities in the United States in public park area proportionate to population, having 1,933 acres valued at \$2,000,000. The city also leads all others in percentage of home owners, 51 per cent of the people owning their homes, according to the United States census. The city has 68 miles of paved streets; 392 miles of graded streets; 633 miles of concrete sidewalks; 144 miles of sewers; 137 miles of gas mains; 137 miles of electric street railways; 1,408 street lights; 356 miles of water mains; 2,260 fire hydrants. The water supply comes from an underground river reached by deep wells, and is among the purest in the world. The death rate in 1915 was 8.14 per 1,000 of population, one of the three lowest among the cities of the United States. Some of the principal buildings are the government building, Davenport hotel, Old National Bank, Paulsen building, public library, city hall, county courthouse, Gonzaga College, high school, Auditorium, Review, Empire State buildings, Masonic temple, Spokane Club building, Spokane Amateur Athletic Club building, Protestant Episcopal and Roman Catholic cathedrals, and the churches and the schools. Fort Wright, a United States military post, is located on a tract of land, 1,022 acres, which the city gave to the government in 1894-95, on condition that a large military post should be established and maintained here. The city is especially noted for its fine residences and paved streets, and is known throughout the Pacific Northwest as the "Home of the Mining Kings."

Education.—Spokane is the educational centre of the "Inland Empire." The schools of higher education are Gonzaga University, Whitworth College, Spokane College and Spokane University. The Catholic Church conducts Saint Michael's scholasticate for the training of priests. There are two high schools and five parochial schools, as well as four business colleges. Four hundred and ten teachers are employed in 35 grade schools. The value of the public school buildings is \$2,505,396.92. Value of building sites, \$740,741.90; school equipment, \$351,762.78. Total school enrolment in 1918 was 20,134. The city maintains a public library and seven branches in residence districts, besides 200 classroom libraries in public and private schools. Value of books and equipment, \$118,000. There are 112 churches of all denominations in Spokane.

Banks and Finance.—There are 13 banks, of which three are national. The combined capital is \$4,325,000; surplus and undivided profits, \$1,354,919; deposits (May 1919), \$46,592,052. Bank transactions in 1918 aggregated \$1,263,198,089; clearings, \$422,346,431. The combined tax rate in 1918 for State, county, city and school purposes was 47 mills, on an assessed valuation of \$108,760,004. Bonded debt, \$4,710,000.

Government.—The city operates under a commission charter and five commissioners, elected on a non-partisan basis. The responsibility is centralized and the work divided under the following headings: finance, public safety, public affairs, public works and public utilities.

Historical.—Spokane's brief history is interesting. The first settlement was made in the summer of 1872, when a handful of sturdy

people gathered at the Spokane River Falls. Earlier it was the home of trappers and hunters, who sold their pelts to the Hudson's Bay Company and the Astors, who in turn maintained the Spokane House, before the Oregon country became part of the United States. But the town did not really get under way until the Northern Pacific arrived in 1881. Eight years later fire devastated the 30 blocks in the business district. It was the first real test and it found the people of Spokane undaunted. Since then its growth has been steady and substantial. The population figures given by the Federal Census Bureau follow: (1890), 19,222; (1900), 36,843; (1910), 104,402; (1914), 135,657. Population in 1919 is estimated at 137,000.

R. A. LAIRD,

Publicity Secretary, Spokane Chamber of Commerce.

SPONDIAS, a genus of tropical trees belonging to the family *Anacardiaceæ*, several of which are cultivated for their plum-like yellow fruit (drupes). The leaves are alternate and odd-pinnate, with numerous leaflets. The flowers are small, polygamous, in spreading terminal panicles, with four or five expanded petals. The leaves and bark have therapeutic value. The fruits of various species are known as hog-plums; they are laxative, and often austere in flavor. *Spondias dulcis*, the pomme de cytheie, sweet Otaheite apple, or wi-fruit, is the golden-yellow fruit of a tree about 50 feet high, common in Polynesia. This fruit has an apple-odor, but a sharp flavor resembling that of a pineapple, and stringy flesh. The Jamaica plum, or golden apple, is another tall tree, with an ash-like aspect (*S. lutea*), with yellowish flower buds which are made into conserve, and an oval drupe. The Spanish plum is the purplish or yellow fruit of *S. purpurea*, widely cultivated in the West Indies. *S. mangifera*, of India, has smooth fruits called wild mango or amra, which is cooked and made into curries, etc.; the tree also yields therapeutical remedies, and a gum resembling gum arabic, and known as hog-gum. The Brazilian *S. tuberosa* not only has a fruit employed in that country as a febrifuge, but is said to produce aerial roots, that, upon touching the soil, form black hollow cellular tubers, containing about a pint of water, which, although intended as a reservoir for the tree in dry weather, serves travelers also.

SPONGE, the horny skeleton, formed of keratose, or spongin, produced by certain animals living in the sea and of very low grade in the scale of life. Down to a quite recent period they were classified as colonial *Protozoa*, the lowest group of animals; but all naturalists now treat them as separate phylum under the name *Porifera* (or *Spongiaria*), given to them because of the water-pores with which they are provided in such abundance. These pores are ordinarily and chiefly of two kinds, both opening into the internal or digestive canals and passages which everywhere ramify through the mass of the sponge. There are large openings (oscula) relatively few in number, often guarded by special protective devices such as circles of spicules or muscles capable of contracting the orifice, and much more numerous small pores everywhere perforating the surface. The latter are inhalent pores or inlets, which admit water to the internal passages, from which it escapes through the former. A con-

stant current is induced by the activity of countless flagella or little living lashes, generally confined to definite enlargements of the canals known as ciliated chambers which constantly beat the water and drive it ever onward in one direction. This current is a veritable life-giving one to the sponge, bearing into the digestive cavities not only the minute organisms upon which the sponge animal feeds, but also supplying oxygen for respiration, bearing away all waste and excreted substances and assisting in the fertilization of the eggs and the distribution of the larvæ. Some of the simplest sponges, such as are found among those with calcareous skeletons, have but a single osculum at the summit of a sac-shaped or cylindrical body, the walls of which are perforated by many radiating canals, each opening to the exterior by an inhalent pore and ending internally in the central digestive chamber. The walls of such a sponge are composed of the sponge-flesh, formerly called sarcode, together with the skeleton secreted by certain cells of the latter. The flesh consists of three chiefly cellular layers, ectoderm, mesoderm and endoderm. The ectoderm is the sponge-skin and, in the form of a layer of flat cells, covers the whole exterior and lines certain spaces or chambers which are formed in many sponges by a process of enfolding. The endoderm lines all of the truly internal chambers and passages, and consists partly of flattened digestive cells which line the central cavity and parts of the radial canals, and partly of cells which bear each a flagellum with a collar surrounding its base on their free ends, and which are confined to the ciliated chambers. These latter collared and flagellated cells are very characteristic of sponges and are found elsewhere only among the *Protozoa*. Between these limiting layers the mesoderm makes up the great bulk of the sponge-body and consists of a variety of different kinds of cells, of which the most important are the reproductive, from which the eggs and spermatozoa are produced; and the skeletogenous, which secrete the elements of the skeleton.

The great majority of sponges are originally of much the form just described, which may be considered as exemplifying the sponge individual; but as they grow they bud and branch in a very plant-like manner, forming many new oscula and many new partial individuals which often reunite and enclose cavities lined with ectoderm. In this manner colonies of large size and most varied forms are built up, and, simple as the fundamental sponge plan is, there are few animals which present more complex structures and whose morphology has been so late in being correctly explained. The skeletons of sponges may be calcareous or silicious or horny, or the latter may be combined with either of the others. The first two may exist in the form of separate spicules, presenting the most varied shapes characterizing the different genera and species, or built up into a more or less continuous frame-work. Horny or sponging skeletons consist of fibres, almost always interlacing, branching and uniting in a most complete and complex manner, and sometimes strengthened by included silicious or calcareous spicules or granules.

Sponges reproduce asexually by a mode of budding and growth similar to that just described or, as especially exemplified in the fresh-

water sponges, by the formation of gemmules which are complexly formed buds protected by a spicule-sheath and capable of developing into a complete sponge colony. They also reproduce sexually by the union of ovum and spermatozoon which develops into a free-swimming ciliated larva (planula), serving not only to reproduce the species but through its activity to distribute these fixed and stationary animals. Except a few small fresh-water species all of the sponges are marine, and occupy all seas from the shores to great depths. It is in tropical and subtropical regions, however, that they are especially prominent. Remains of fossil sponges in great number and variety, some of them representing extinct types, occur in all geological formations from the Cambrian upward.

The phylum *Porifera* has been classified as follows:

Class I. *Calcarea*, including sponges with calcareous spicules, such as the little *Grantia ciliata*, so common on the New England coast.

Class II. *Hexactinellida*, including sponges with silicious usually six-rayed spicules, such as glass sponges and the beautiful Venus' flower-basket (*Euplectella*) of the Japanese and Philippine seas.

Class III. *Desmospongiae*, including all other sponges with horny or silicious skeletons, and divided into the following three grades: (1) *Tetraxonida*, with tetraxial silicious spicules; (2) *Monaxonida*, with uniaxial spicules, including the fresh-water sponges. (3) *Keratosa*, with a skeleton of spongin fibres, including all of the commercial and related sponges.

The sponges of commerce come from the eastern Mediterranean Sea, the West Indies, and the coasts of Florida and Central America. In the Grecian Archipelago, Crete, Cyprus, on the coasts of Asia Minor, Syria, Barbary and the Bahama Islands, sponge fisheries constitute a very important industry. The finest sponges are obtained in Turkish waters. The fishing season commences in May and closes in September or October. Diving is practised and is carried on in a rude, primitive manner. The diver, who has no dress, seizes hold of a large stone, to which a line is attached, and sinks by means of it to a depth varying from 30 to 180 feet. Keeping hold of the rope, he tears the sponges off the rocks within his reach and places them in a net; when he has secured a netful he signals by means of the rope to be drawn up.

Modern diving dresses have been introduced successfully in some places. The West Indian trade is annually increasing and the fishing industry gives employment to 500 boats and over 2,000 persons. The Bahamas and the coast of Florida are the best fishing grounds.

Florida is the only State in the Union which has a sponge-fishery, and there it is confined to the southwestern part of the coast, along the reefs and to the extensive rocky shoals that lie between Saint Mark's and Anclote Keys. The former is known as the Key ground, with its centre at Key West, the latter as the bay ground with its centre at Tampa Bay.

Nearly all of the sponges used in the United States were brought from the Mediterranean till 1852, when attention was called to the immense numbers that were growing in Florida waters. As soon as it was found that the qual-

ity of these compared favorably with those of Europe the merchants and fitters-out of vessels of Key West engaged very actively in the business of placing them on the market. At first the best qualities were bought from the fishermen at the rate of 10 cents per pound. As Mediterranean sponges became scarce and costly the Florida sponges came into more and more demand and their value increased proportionately. After about 18 years' fishing on the known ground the supply began to fail. Then, in 1870, a new area of ground, larger than the old one, was discovered, and this gave a new impetus to the trade. In that year Appalachicola sent out a small fleet of sponge vessels which has since been largely increased and the industry has been energetically pursued with good results.

The methods employed in the fishery differ greatly from those employed in the Mediterranean. Small vessels, carrying crews of from 5 to 15 men, are fitted out for trips of from four to eight weeks on the sponge grounds. The crews are paired off into small rowboats, or "dingies," to catch the sponges. One man stands in the stern, sculling the boat, while the other kneels in the bottom amidship, leaning over the side and scans the bottom of the sea by the aid of a water-glass. When a sponge is sighted the boat is stopped and the kneeling man uses a three-pronged hook, attached to a slender pole 30 to 50 feet in length, to secure it. Considerable dexterity is required of both men. To cure the sponges they are first spread about the vessel's deck in their natural upright position, so that they will die, and while decomposing allow the softened animal matter to run off freely. When they have been several days in this position they are taken to the shore and thrown into the water in little pens called "kraals" (corrals) where the remaining substance is soaked and squeezed out, after which the sponges are removed at intervals and beaten with a stick to facilitate the process.

Although most actively prosecuted during the summer, sponge fishing is now followed more or less throughout the year, the vessels beginning their trips in January and working the different beds successively from north southward. The state of the weather greatly affects the result of the fishery. In some years it has been a complete failure, while in others it has been very profitable, always owing to the weather. As the natural beds of sponges have become scarcer prices have advanced, so that even if a vessel does not secure as large a quantity in a given time as formerly the financial result is about the same.

Several varieties of sponges are caught in Florida waters. There are first, sheep's wool, which sell for \$2 to \$5 a pound; second, yellow sponges, which sell for 50 to 60 cents per pound, and third, grass sponges, which are coarse in texture and not durable, and sell for 15 to 25 cents per pound. Other coarse grades are boat and glove sponges. When these are marketed they are trimmed and cleaned of sand and shells and then pressed into small bales of 100 to 120 pounds each, in which form they go to the wholesale dealers. The yellow sponge especially is subjected to a bleaching process to improve the color, but the process ordinarily employed greatly weakens the fibre.

Owing to the rapidly decreasing supply of

the finer grades and the rising price the problem of propagating sponges artificially has been taken up seriously by the United States Bureau of Fisheries. It has been found that sponges may be raised successfully both from the egg and from cuttings, but, owing to the much shorter time required for the latter to reach a marketable size, the first method has been abandoned. The technical problems of sponge raising have been largely solved and there is every promise that their culture on a commercial scale can be undertaken in the near future and that the depleted grounds will be restocked.

The Florida sponge fisheries employ about 2,245 persons, with 156 vessels and other apparatus valued at \$594,598. The average annual product aggregates 418,125 pounds of all kinds of commercial sponges, which sell for \$567,685. To this total, sheep's-wool sponges contribute 181,311 pounds, valued at \$483,263.

SPONGE-CUCUMBER. See FIBRE.

SPONSORS, in the American Church, those persons who at the solemn administration of baptism make profession of Christian faith on behalf of the baptized. The sponsors are also called godfathers and godmothers of the neophyte; and as the sponsors are regarded as having contracted a spiritual relationship among themselves and with their godchild, they used also to be called godsips (gossips). Sponsors assist at the baptism of adults as well as of infants; but in the baptism of adults those to be baptized, not the sponsors, make answer to the questions put by the minister of the sacrament, "Dost thou renounce the devil and all his works," etc. By a decree of the Council of Trent two sponsors at most are permitted, a male and a female. In the Anglican Book of Common Prayer it is prescribed that for every male child to be baptized two godfathers and one godmother shall assist, and for every female child one godfather and two godmothers; the same rule applies in the baptism of adults.

SPONTANEOUS COMBUSTION. See COMBUSTION, SPONTANEOUS.

SPONTANEOUS GENERATION, the doctrine that living matter may originate spontaneously, that is, out of non-living matter. The sudden appearance of living things in dead

bodies, as of maggots in flesh, and mold on vegetables, was formerly accounted for by regarding them as the direct products of the decay or putrefaction in which they occurred, through some unexplained process. The Italian experimenter, Spallanzani (q.v.), first indicated the probability of the source of these growths being living things or their germs pre-existing in the atmosphere. He found that when he bound organic solutions, as beef-broth or an infusion or "tea" of hay in a vessel closed against the admission of air, no appearance of living beings, or any evidence of "generation" followed; and the same freedom continued when the air which entered vessels containing fermentable solutions was made to pass first through sulphuric acid, through red-hot tubes, and through cotton-wool. That the air does actually contain large quantities of minute organic bodies was demonstrated by Tyndall in his efforts to obtain optically pure atmosphere, and this explains why preserved meats keep for any number of years if properly closed, since, after their thorough cooking, the apertures are hermetically sealed while steam is still escaping, the entrance of atmospheric air with its contents being thus prevented. Lister's antiseptic treatment in surgery is based on the same hypothesis.

But while spontaneous generation is untenable as an explanation of phenomena now in progress, science knows nothing of the original development of living things. Some scientists have held that life comes to the earth from other planets by light pressure moving excessively minute forms. Others have advanced the theory that there is a life element in nature not appreciable to man's five senses, but which under right conditions brings vegetable, animal and human life into matter. Until we know what life is no theory of spontaneous generation will maintain. Evolution is incomplete as a scheme of the universe without the hypothesis of spontaneous origin of living things from inorganic matter. Therefore, many regard life as a problem to be solved only by occult means or by the reincarnated man after the death of his physical body. This is a matter in which chemistry must be consulted as well as biology; and the opinions of thinkers in respect to it—in general an attitude of waiting for more light—may be found under such heads as ANIMAL; ANTISEPTIC; BACTERIA; EVOLUTION; LIFE; PROTOZOA.

SPONTINI, spōn-tē'nē, *Gasparo* ("LUIGI PACIFICO"), Italian composer: b. Majolatti, Italy, 14 Nov. 1774; d. there, 24 Nov. 1851. He was educated at the Conservatorio della Pietà d'Turchini at Naples and at 17 produced his first opera, 'Puntigli delle donne,' which met with immediate success. He went to Paris in 1803, was appointed musical director to the Empress Josephine in 1807, and in 1810 became director of the Italian Opera. In 1820 he accepted the position of court composer and general musical director at the court of Prussia and entered upon a brilliant career at Berlin. His intense jealousy of Weber aroused popular feeling against him in the latter years of his sojourn in that city, and in 1841 he was removed from office though retaining both title and salary. He had been elected one of the five members of the Académie des Beaux Arts at Paris in 1839 and in 1842 he returned to that

city. His operas met with continued and brilliant success and he is generally considered the greatest composer in French tragic opera between Gluck and Meyerbeer. His operas include 'L'eroismo ridicolo' (1797); 'La vestale' (1807); 'Nurmahal' (1822); 'Alcidor' (1825); 'Agnes von Hohenstaufen' (1829), etc.

SPOOL, a small cylinder, usually of wood and with a hollow centre, with expanding ends, on which thread, cord or yarn is wound; also any small creel, reel or bobbin used for winding. Machines for winding thread on spools are termed spooling machines or spoolers.

SPOONBILL, a wading-bird of the family *Plataleidae*, closely related to the ibises, from which the group differs principally in its straight grooved bill, which is quaintly flattened and expanded at the end. The three genera, *Platalea*, *Ajaja* and *Platibis*, comprise about eight species found in all warm countries. The only American species is the roseate spoonbill (*Ajaja ajaja*). At present it is found throughout South America and northward into the South Atlantic and Gulf States, but formerly ranged to Virginia and Illinois. The general form is heron-like but stouter; the length somewhat less than three feet, the wing expanse about four and one-half feet; the color is white tinted with rose, which becomes quite deep on the under parts, with rusty yellow patches on the tail and sides. The head is bald and variegated with black, green, yellow and orange colors; the bill similarly colored with the addition of blue; the legs and iris red. Young birds lack the rosy tints and have the head fully feathered. This singular and brilliant bird lives gregariously in wooded swamps, and is still abundant in parts of South America and the more inaccessible parts of Florida, but has been exterminated in many places where it was formerly plentiful. They wade in the water and sweep their bills sideways through the mud in search of fishes, frogs, crustaceans, mollusks, insects and worms, upon which they feed. They are strong but heavy in flight and are able to swim somewhat. Besides their harsh cry they produce a clattering noise by snapping the bill like storks. Nesting takes place in colonies, the nest being constructed of twigs in trees and bushes. The three white, rough, elliptical eggs, more than two and one-half inches in length, are laid in April. The European spoonbill (*Platalea leucorodia*) is widely distinguished throughout southern Eurasia, but formerly bred in England. Except that the head is crested and the color chiefly white it closely resembles our species in appearance and habits.

The name spoonbill is also given to a duck (see SHOVELER), and to a sandpiper (q.v.).

SPOONER, John Coit, American legislator: b. Lawrenceburg, Ind., 6 Jan. 1843. He removed with his parents to Madison, Wis., in 1859, was graduated from the University of Wisconsin in 1864, and then enlisted as a private in the Union army. He was mustered out of service as brevet-major, and in 1870 established himself in a law practice in Hudson, Wis. He was elected to the State legislature in 1872, served in the United States Senate in 1885-91, and again from 1897-1907, resigning in March 1907, and engaging in the practice of law at No. 14 Wall street, New York City.

SPORADES, spŏr'a-dēz, either of two groups of islands east of Greece, which have been known by various names at different periods. The Northern Sporades lie east of the Gulf of Volos, and their modern names of the larger areas are (in the order of size) Skopelos, Skiathos, Khilodromia, Pelagonisi and Giuri. They have a total area of 180 square miles, and about 13,000 inhabitants. Every householder on the islands is said to own a ship or boat. The Southern Sporades lie in the Jesaireh-Bahr-i-Sefid Archipelago, east of the Cyclades and south of Asia Minor, Icaria, Astrophalia and Leros are the largest, while Creti, Rhodes and Patmos are the most famed. The largest population is in Icaria (8,000) and Calymnus (7,000). See PATMOS.

SPOROBOLUS. See GRASSES IN THE UNITED STATES.

SPOROLOGY, a form of reproduction by spores. See SPOROZOA.

SPOROPHYTE, Evolution of. Some botanists are still disputing in regard to those earliest stages in the evolution of the sporophyte which are found in the algæ and fungi; but there is complete agreement that in all plants from the liverworts and mosses to the sunflowers and orchids the sporophyte begins with the fertilized egg. (See ALTERNATION OF GENERATIONS). Leaving out the algæ and fungi and beginning with the liverworts, the evolution of the sporophyte can be traced with more or less certainty. Before considering the details of development, it may be said that, in such early stages of evolution as are seen in the liverwort and mosses, the sporophyte has no leaves or roots and is dependent upon the gametophyte throughout its lifetime. In the ferns and their allies, the sporophyte is dependent upon the gametophyte during its early embryology, but soon develops leaves and roots and becomes completely independent of the gametophyte, which then dies and disappears. In the seed plants, the gametophyte is the parasitic generation and contributes very little to the sporophyte, except during the first few divisions of the fertilized egg. Several of the most fundamental features in the evolution of the sporophyte are seen in the liverworts. In *Riccia*, one of the lower liverworts, the sporophyte is a small, globular body about one-sixteenth of an inch in diameter, and consists of a central mass of spores surrounded by a single layer of cells (Fig. 1. A). The significant fact is that the entire product of the fertilized egg, except a single, protective outer layer of cells, produces spores. Theoretically, the earliest sporophyte should be one, all of whose cells produce spores. In *Riccia*, a single outer layer of cells has been diverted from the spore producing function, to serve as a protective layer. Botanists speak of this diversion as the "sterilization of sporogenous tissue." The evolution of the sporophyte is marked by more and more sterilization of sporogenous tissue, so that less and less of the product of the fertilized egg is devoted to the production of spores. In some liverworts, all the spores are derived from one-half of the fertilized egg, all the cells derived from the other half being diverted to a vegetative function. This is

shown, diagrammatically, in Fig. 1. *B*, where *s* indicates the spore tissue and *v* the diverted, or vegetative tissue. In most liverworts, even less of the product of the fertilized egg develops into spores, not only one-half, but a large part of the other half being diverted to a vegetative function. This diverted portion forms a "foot" which acts as an absorbing organ, and a stalk, which becomes much elongated and places the spores in a more favorable position for dispersal when they are shed (Fig. 1, *C-f*, foot; *s*, stalk; *sp*, spore

FIG. 1.

tissue). In many forms, even in the spore region, some of the cells become diverted to a nutritive function or aid in the dispersal of spores. In *Anthoceros*, a much studied liverwort, there is a still further sterilization of sporogenous tissue, a central column being diverted to vegetative purposes, so that the spore tissue forms only a thimble-shaped mass, the lower part of which is shown, in longitudinal section, in Fig. 1, *D*. In this case, the youngest spore tissue is at the bottom and the mature spores higher up, a continuous growth in the lower portion resulting in somewhat prolonged period of spore production. In the mosses, there is still further sterilization, so that a comparatively small portion of the sporophyte produces spores. In all these sporophytes, there is more or less green tissue, so that there is some advance toward independence; but there are no leaves and the sporophyte lives and dies with its foot attached to the gametophyte. The simplest form among the ferns and fern allies has a root, stem and leaf, and so is independent. There is no form intermediate between a sporophyte without a leaf and a sporophyte with a fairly well developed leaf. Consequently, the origin of the leaf is still a problem. In the ferns, the spore tissue is not only greatly restricted, appearing only as the "fruit dots" on the underside of the leaf, but it often appears late in the life history of the plant. In the flowering plants, there is still less spore tissue and it may appear still later in the development of the plant. In some of the cycads, the plant may reach an age of 25 years, or even more, before any spore tissue is produced. There is such a tremendous difference between a flowering plant and the small, simple sporophyte of *Riccia*, that it hardly seems possible that the large, complex form could represent a final

stage in an evolution resulting from a progressive sterilization of sporogenous tissue. However, this is the most generally accepted theory of the evolution of the sporophyte. Consult Bower, F. O., 'The Origin of a Land Flora'; Campbell, D. H., 'Mosses and Ferns.'

CHARLES J. CHAMBERLAIN,
University of Chicago.

SPOROZOA, a group of protozoa, ranked as a class or more recently as a phylum, which is composed exclusively of parasitic species. They are characterized by complete absence of structures common in free-living protozoa, viz. (1) locomotor processes, pseudopodia, flagella and cilia, (2) openings for taking in solid food or ejecting waste, so that nutrition is purely osmotic, and (3) contractile vacuoles. The life cycle always includes a period in which a large number of spores is produced, and usually two such periods alternate; in one spores are produced asexually by schizogony and in the other by a so-called sexual process (sporogony). These two occur in different organs if not in different hosts so that alternation of generations is regularly associated with alternation of hosts. The development is often extraordinarily complex and no decision as to position or relationships can be reached until the life history is worked out. As this has been done in but few cases the classification and description of the group is subject to constant and marked changes. The sexual phase which may involve isogametes or heterogametes is regarded as more significant than the asexual in deciding relationships.

The class Sporozoa, as originally conceived by Leuckart (1879), embraced not only the Gregarinida, Coccidioidea, and Hæmosporidia which later Schaudinn grouped together as Telosporidia, i.e., those forms producing spores at the close of a stage in the life cycle; but also the Neosporidia which produce spores continuously. The latter which have amoeboid spores and one or more polar capsules, are now grouped in a separate class, the Cnidosporidia, by many. They include the orders Myxosporidia, Microsporidia, Actinomyxidia, Sarcosporidia and Haplosporidia.

The Gregarinida are chiefly arthropod parasites. They begin the asexual stage as intracellular parasites in the intestinal wall and desert the cells to become adult in the intestine of the host. They are elongate and the cell is often divided into two regions by a cross partition. The gametes are similar or dissimilar.

The Coccidioidea parasitize epithelial cells of vertebrates particularly in the alimentary canal and its glands. In form they are spherical or nearly so and without differentiated ecto- and endoplasm. The host cell shrinks as the parasite grows until it is reduced to an empty cyst membrane within which the parasite breaks up into a number of crescentic spores surrounding a central residual mass. By rupture of the membrane these merozoites are scattered to infect new cells. At times some stimulus, perhaps excessive infection, leads to the production of micro- and macrogametes which fuse in pairs to form sporoblasts and these encysting became sporocysts in which are produced sporozoites. The latter are the agents by which new hosts are infected and their production

takes place usually outside the host. The Coccidioidea cause serious epidemics in rabbits, hares and other animals; they occur in many hosts, even including man.

The Hæmosporidia are clearly coccidia which have been adapted for life in the blood. The asexual stage is amœboid in the red blood corpuscles where merozoites are produced that infect other corpuscles, repeating the process until gametes are formed that await a change of host to find opportunity for further development. This is given by withdrawal of the blood into the stomach of some biting insect where the gametes complete their development and fuse. The sporoblasts and in them the sporozoites are formed in the wall of the insect's stomach and when the sporozoites are set free they penetrate the salivary gland and proboscis by which in the act of biting they are introduced into a new host. (For further details and illustration see article PLASMODIUM). The most famous members of this group are the organisms producing malarial fevers in man of which there are at least three distinct types. Other species occur in birds and related genera in Amphibia, fishes and reptiles. The mosquito (q.v.) is the inoculating agent for malarial fevers, and since it shelters the sexual generation must be considered the primary host whereas man is the secondary. A leech is believed to play a similar rôle for certain species parasitic in fish. Probably the most widely known disease among domestic animals which is caused by a member of this group is Texas fever in cattle, transmitted by the cattle ticks. See RINDERPEST.

The Myxosporidia are practically exclusively fish parasites. Certain forms are common in the gills, others in the skin, where they form conspicuous masses. Less well-known forms inhabit the gall bladder or form ulcers in the muscles and are the cause of serious diseases. The Myxosporidia possess polar capsules which resemble much the nettling cells of Coelenterata.

The Microsporidia are not well known despite the fact that they are of conspicuous economic importance since one species is the cause of Nosema, a serious disease of the honey bee and another produces pébrine of the silkworm; the latter was the subject of early important studies by Louis Pasteur.

The Sarcosporidia are found parasitic in the muscle cells of vertebrates and are sufficiently large to be conspicuous to the naked eye. They were originally designated Miescher's or Rainey's corpuscles and occur occasionally in man. A serious Australian disease of sheep known as "scrapie" is caused by one of these forms; it is also found in North America. By dissecting Sarcosporidia out of host tissue and subjecting them to chemical study a protozoan toxin named Sarcosporidin has been isolated; this is the first discovered in this group.

HENRY B. WARD,
Professor of Zoology, University of Illinois.

SPORRAN, a pouch or large purse worn by the Highlanders of Scotland in full dress, and by men of the kilted regiments. It is usually made of the skin of some animal, with the fur turned out, and often ornamented with silver and stones. It is worn in front of the kilt. The name is the Gaelic for purse.

SPORTING RECORDS. See SPORTS.

SPORTS, The Book of, a popular name for the proclamation issued in 1618 by James I, and ordered to be read in all churches, wherein it was declared that dancing, archery, May-games, morrice-dances, leaping, vaulting and other such games were lawful on Sunday after divine service, but prohibiting bear-baiting, bull-baiting, bowling and interludes. The order to read this declaration was largely disregarded, but in the reign of Charles I it was republished (1633) and enforced with severity. This created great outcry and opposition and in 1644 the Long Parliament ordered all copies of it to be collected and publicly burned.

SPORTS: THEIR DEVELOPMENT, SPEEDS AND RECORDS. In the state of savagery man's life depended on his agility in running, jumping, climbing and throwing of projectiles. In the high condition of civilization of ancient Greece the natives considered prowess in the arts of speed and endurance as evidence of superiority in manhood and they held their athletic sports in reverence as well as with enthusiasm. In their Olympic or Pan-Athenaic Games the entire populace partook. A proof of all-round manly vigor was given in their *pentathlon*, which consisted of a series of five games contested by the same rivals—running, jumping, wrestling, disc-throwing and javelin throwing. In recent years we have established a renewal of these ancient sports as well as that of the Marathon races. The latter covers a distance of 26 miles, 385 yards, and some of the records are as follows: Olympic Marathon, held at London in 1908, was won by the American John Hayes in 2:56:02 2-5; in the same year at Madison Square Garden, run by the Italian Dorando against Hayes, the former won in 2:44:20 2-5. J. T. Crowley of the Irish-American A. C., won the race at Yonkers, same year, in 2:49:16 2-5. In the amateur race from Rye to Columbus Circle, New York, Matthew Maloney of the Trinity A. C. won in 2:36:26 1-5. Of marvelous interest would be a comparison of the speeds and records achieved in sports by the ancient Greeks and Romans with those of our day. Only a few records of classic day sports have come down to us, however, and these pseudo-records can only amuse and surprise us. In leaping or long jump (termed *halma*) the ancients used weights (called *halteres*) like our dumbbells to increase their capacities, and we have the record attributed to a certain athlete named Phayllus of Kroton of 55 feet. This looks like the measure of our hop, skip and jump. And we are never likely to achieve what these sporting reporters recorded with their elasticity of statement. Our records are scientifically measured and corroborated by expert unbiased judges or are ignored as "unofficial."

The outcome of the supreme efforts of man in recent days in running, walking and some

other contests will be found in the last section of this article under the head "World's Sports Records." These tables afford a record of the advance man has made in speed by science and physical development. The following statistics give the various records to date.

TROTTING HORSES.

Trotting.—The "foundation" horses or first sires of the American trotting track were the imported stallions Messenger and Justin Morgan (former died 1808; latter 1821). Hambletonian, a descendant of Messenger, headed a great family of thoroughbreds, and the Justin Morgan breed includes many noted trotters of this day. Of old records that can be relied on we have: Three miles under saddle, Screwdriver, 1828, 8:02; three miles in harness, Topgallant, 1829, 8:11; 1834, Edwin Forrest, one mile under saddle in 2:31½; same year Sally Miller, one mile in harness in 2:37; 1845, Lady Suffolk, one mile in harness in 2:29½; 1849, Pelham, one mile in 2:28. Noted one mile high wheel records are: Maud S., 1885, 2:08¾; Sunol, 1891, 2:08¾ (kite track); Palo Alto, 1891, 2:08¾ (kite track); Jay-eye-see, 1884, 2:10. In 1892 the bicycle sulky arrived.

Records under saddle are: One mile, Great Eastern, 1877, 2:15; two miles, George M. Patchen, 1863, 4:56; three miles, Dutchman, 1839, 7:32½; four miles, Dutchman, 1836, 10:51.

Noted one mile trotting records with running mate are: Ayres P. (against time), 1893, 2:03¾; Frank (in a race), 1883, 2:08½. **One mile team** records are: Monk and Equity, 1903, 2:08; Leaf and Sally Simmons (in a race), 1894, 2:15¾; Uhlan and Lewis Forrest, 1912, 2:03¾. For world's records see last section of article.

Harness speed (one mile): Boston Blue, 1818, 3:00; Bull Calf, 1830, 2:47¾; Edwin Forrest, 1838, 2:36¾; Dutchman, 1839, 2:32; Lady Suffolk, 1845, 2:29½; Pelham, 1849, 2:28; Highland Maid, 1853, 2:27; Flora Temple, 1859, 2:19¾; Goldsmith Maid, 1871, 2:17; Rarus, 1878, 2:13¾; Maud S., 1880, 2:10¾; Jay-eye-see, 1884, 2:10; Maud S., 1885, 2:08¾; Nancy Hanks, 1892, 2:04; The Abbott, 1900, 2:03¾; Cresceus, 1901, 2:02¾; Lou Dillon, 1903, 1:58½ (with shield); Uhlan (with running mate), 1913, 1:54½. In 1892 the bicycle sulky brought the record down quickly and in 1903 we meet the supposed impossible two-minute horse, Lou Dillon. For world's records see last section of article.

PACING HORSES.

These were brought into popularity when the country was young and roads bad; the saddle-horse of easy gait was then of great use. The Rhode Island pacers, called Narragansetts, are claimed to be from Spanish (Andalusian) stock. The Kentucky and Tennessee pacing horses are said to have come from Canada, and they were never trained to harness till recent dates. Records to 1902 are: Star Pointer, 1:59¾; Dan Patch, 1:59½; Prince Alert, 2:00, etc. The dirt shield aided Dan Patch to attain 1:56¾ in 1903. For fastest speeds see table of "World's Records" in last section of article.

YACHTING RECORDS.

Our earliest yachting records take us back to 1801 when Capt. George Crowninshield of

Salem, Mass., got Christopher Turner of that town to build him *The Jefferson*, a 22-ton sloop yacht. This craft in 1812 became a privateer, then for many years a fisherman. George's brother, Benjamin, then Secretary of the Navy, under President Madison, had the *Cleopatra's Barge*, with a 93-foot waterline, of nearly 192 tons, 11 feet 5 inches depth of hold, built at a cost of \$50,000. In this pleasure craft Captain Crowninshield made, in 1817, a cruise to European waters, returning same year. Between 1830 and 1840 we find numerous pleasure craft in New York and Boston, with John C. Stevens (owner of Hoboken Island on the Hudson), George Crowninshield and R. B. Forbes leaders in the sport; but it was chiefly with ship-owning families. George Steers, son of an English shipwright, modeled the schooner yacht *La Coquilla*, 44 feet in length, and (in 1847) modeled and built the schooner *Cornelia* (74 feet). Then were constructed by him the schooner *Signet* (53 feet, 2 inches) and the sloop *Una* (64 feet). This was probably the commencement of designing boats on special lines as pleasure craft. This "boom" in yacht-building started the New York Yacht Club in 1844, and Stevens and Steers are considered the fathers of American yachting. In 1849 Steers modeled the *Mary Taylor* as a pilot-boat on radically novel lines so successfully that others followed on his new plans. On 17 July 1845, two days after the New York Yacht Club built its (wooden) clubhouse at Castle Point, Hoboken, the first regatta was sailed (Robbins-Reef to a Bay Ridge mark, past a Stapleton mark, around Southwest Spit buoy and return) with eight entries and *Cygnets* winning in 5:23:15. Regattas continued annually. The Southern Yacht Club of New Orleans was organized in 1849; North Carolina Yacht Club in 1854; Brooklyn Yacht Club in 1857, and Jersey City Yacht Club the following year. Between 1866 and 1872 yachting had become so popular that general clubs were formed all along the Atlantic Coast. In 1851 George Steers designed and a "syndicate" had built an ocean-going \$30,000 yacht in pilot-boat style, 101 feet long over all, drawing 11 feet, to enter a yacht race around the Isle of Wight, England, following an invitation from the British. The yacht was christened *America*, and sailed to Havre in 21 days. The story of *America's* victories belongs elsewhere, but Commodore Stevens and associates brought the Royal Yacht Squadron's Cup to New York, where it has resided ever since. The *America's* model and sails established a new departure, followed by British as well as American yachts, and the old blunt noses gave way to keen prows (John Scott Russell, British designer, had first advocated these revolutionary changes before the *America's* construction, and Steers had studied the suggestions). But centre-boards prevailed over keel boats for these shallow waters. The cat-boat was a favorite small craft in the 50's of last century, and Capt. Bob Fish designed many for Europe (where they were called "Una" boats) besides large yachts later (*Gertrude*, *Undine*, etc.). In the 60's John B. Herreshoff and family made Bristol, R. I., noted with his small and larger yachts, then launches and steamers. And James G. Bennett with his *Rebecca* (sloop) racing the *Julia* (recently named *Nirvana*), the centre-board sloop, Bos-

ton also became a favorite yachting centre. The great schooner yachts came into vogue after the Civil War (*Fleetwood*, *Phantom*, *Palmer*, *Josephine*, *Idler*, etc.). And in 1866 Pierre Lorillard had his 201-ton *Vesta* built. Then came the ocean race (winter of 1866) from Sandy Hook to Isle of Wight, *Henrietta* (of J. G. Bennett), *Fleetwing* and *Vesta* contesting (times, respectively, 13d. 21h. 55m.; 14d. 6h. 10m.; and 14d. 6h. 15m.) over the 3,000 and odd miles course. The 274-ton *Sappho* (keel schooner), built by Poillon Brothers and launched in 1867, was a failure at Cowes races till W. P. Douglas had her altered and made the run to Queenstown in 12d. 9h., a record, and beat Ashbury's *Cambria*. By 1870 schooner racing was the vogue but the "skimming dish" type was coming into its own, with its light draught. The *Mohawk* disaster (costing the lives of owner and family) hurt the large schooner type. The "America Cup" races following do not belong here. In 1871 the Seawanhaka Yacht Club was organized and yacht owners began to take a pride in knowing the technique of the craft, not leaving, as before, everything to the professional designer. Then the English "cutter" type was started in the *Vindex* (1871), and other seaworthy yachts followed, with *Petrel* (1876), *Volante* (lead keel), etc., proved successes; and "Corinthian" principles ruled. The lead keel brought in the narrow type such as *Muriel* (1878). *Mischief* ("compromise sloop") of 1892 was cutter type with centre-board. Next came racing by classes (all entered one race), and schooner and sloop entered separate classes. The latter, in the late 70's divided into 70 footers and 50 footers. Hulls of metal started with *Mischief*. In 1881 came *Valkyr*, wider and with less draught, lead keel, centre-board, cutter rigged. *Madge* (10 toner, lead keel) came from Glasgow (1879) as victor in England and Scotland, and, with her great club-topsail, took on a speed that won all New York Harbor events, only to be beaten by *Shadow* (Herreshoff) at Newport. But six victories in seven races hurt the reputation of centre-board sloops and cutter type looked up. Will Fife, Jr.'s, 62-foot *Clara*, narrow cutter, came from Scotland in 1885 and (under Capt. John Burr) defeated everything competing. Burgess was the popular designer now (*America* Cup defenders 1885, 1886, 1887), and yachting was the most popular sport, the races being prolific in classes: 90 feet, 70 feet, 53 feet. Forty-foot waterline boats became the rage (*Baboon*, *Nymph*, etc.), and the 40-foot *Minerva* came over from Scotland (1888), beating *Liris*. Burgess produced *Gossoon* (keel) and they tied in 10 races. After 1890 the 90-foot class was superseded by the 46-foot waterline craft. Herreshoff's *Gloriana* now became the furor with its abnormal projection of shallow bow, the "forefoot" cut away; then he produced the "fin" keel (1892). Space does not permit discussion of the "small yachting" types (*mosquito*), half-raters, "knockabouts," etc.

On account of the World War yacht-racing had to fall into disuse after the *Shamrock IV*, contestants, *Vanitie* and *Resolute* had made trial speeds in 1915, but Sir Thomas Lipton renewed his challenge in 1919 and his challenger is expected to be taken from her Erie Basin dock for her next year's race.

MOTOR BOAT RACING.

Competition has been keen in this most modern of aquatic races, and the development in speed is phenomenal. The popular National Power Boat Association championship Gold Cup races (30 miles) show the following winners:

Date	Winner	Owner	Average speed
1912	P. D. Q. II.	A. G. Miles	36.8
1913	Ankle Deep	Count Mankowski	44.5
1914	Baby Speed Demon II.	P. Blackton	50.49
1915	Miss Detroit	D. P. B. A.	48.49
1916	Miss Minneapolis	M. P. B. A.	49.27
1917	Miss Detroit II.	D. P. B. A.	54.36
1918	Miss Detroit III.	Detroit Y. C.	34.10

For other records see World's Records section at end of article.

STEAMSHIP SPEEDS.

Transatlantic Records.—In the days of the fast-sailing packet ships the old *Yorkshire* crossed from Liverpool to New York in 21 days, and *Ashbourn* made the passage in 24 days. With our modern "greyhounds" of the ocean the following records show the ever-increasing speed of the liners between New York and Queenstown: 1856, *Persia*, 9d. 1h. 45m.; 1856, *Scotia*, 8d. 2h. 48m.; *City of Brussels*, 7d. 22h. 3m.; 1873, *Baltic*, 7d. 20h. 9m.; 1876, *Germanic*, 7d. 11h. 37m.; 1880, *Arizona*, 7d. 7h. 23m.; 1882, *Alaska*, 6d. 18h. 37m.; 1884, *Oregon*, 6d. 11h. 9m.; 1887, *Umbria*, 6d. 4h. 42m.; 1888, *Etruria*, 6d. 1h. 55m.; 1891, *Majestic*, 5d. 18h. 8m.; 1891, *Teutonic*, 5d. 16h. 31m.; 1893, *Campania*, 5d. 12h. 7m.; 1894, *Lucania*, 5d. 7h. 23m.; 1909, *Mauretania*, 4d. 13h. 41m. In 1910 *Mauretania* made the trip from Queenstown to New York in 4d. 10h. 41m. *France* made the passage from New York to Havre, 1912, in 5d. 17h.; *Kaiser Wilhelm der Grosse* crossed from New York to Cherbourg, 1900, in 5d. 16h., and from New York to Southampton, 1897, in 5d. 17h. 8m. The voyage from New York to Plymouth was made, 1909, by *Kronprinzessin Cecilie* in 5d. 7h. 25m. Passage from New York to Naples was made, 1904, in 7d. 16h. 44m. by *Deutschland*. The Allen Line *Virginian* (turbine), 1905, crossed from Mobile and passed Cape Race in less than four days.

Of recent years the aim of the great transatlantic steamship lines to reduce passage time and make new records has died out under compelling circumstances. The advance in speed is gained, of course, by the increase of fuel consumption, but that increase is based on a progressive ratio of augmented consumption, and the cost of fuel together with loss of freight space in carrying such enormous quantities brought the competitors face to face with an actual loss, even at the advanced passenger rates on such "express" steamers. The designers of late have expended their energies in increasing the size and carrying capacities of the leviathans and improving the life attractions on board. And the clipping of hours from passage time must be reckoned as an activity passed into desuetude.

AVIATION RECORDS.

The permanent success of the Wright brothers' invention was proven in 1905 by long distance flights in England, France and Ger-

many, and the armies of these powers grasped the merits of the revolutionary discovery of flight in heavier-than-air machines for war purposes. The governments aided advancement in the new art so that air squadrons soon entered the conflict when the World War reached its fiercest stage. But the war paralyzed competition in popular races and records have not been accepted by the International Aviation Association since 1914. The enormous impulse in advancing the science of aviation caused by the use of the machines by the belligerent governments becomes clear to us when we read the few wonderful feats performed by the improved types of flying structures. Some former prominent events were: The Paris-to-Madrid race won by Vedrine in 37h. 26m. 12s. in 1911. In 1910 Grahame-White had covered 100 kilometers (62 miles) at Belmont Park in 60m. 47 $\frac{3}{4}$ s. or 61.3 miles per hour. The United States army in 1911 had her first intercity race, from New York to Philadelphia (about 83 miles) which was won by L. Beachy in two hours (net time 1h. 50m.), and G. Fourny accomplished in that year 447.3 miles at Buc, France (without stops) in 11h. 29s. Against these records we have in 1918 (when the United States army inaugurated first airplane mail service) the New York to Washington route performed in 3h. 30m. Mail aviators flew last year (with mail) from Paris to London and return in 3h. 10m. In a long series of runs between New York and Washington in 1919 the mail planes have averaged a speed of 70.80 miles per hour. In the revived English aerial Derby, which was interrupted by the war, the course of which is around the suburbs of London, Captain Gathergood, in 1919, won, averaging a speed of 140 miles an hour. T. Sopworth won that of 1912 (in a Bleriot) at an average speed of 59 miles an hour. In 1913 Gustav Hand won it (in a Morane) at an average speed of 76 miles an hour, and an American, W. L. Brock, won the 1914 contest at a speed of 72 miles the hour. For altitude flights January, 1919, Captain Lang, British army, held the record with a height of 30,500 feet. On 28 May this year Adjutant Casale ascended 31,000 feet and on 8 June beat his own record with a flight of 31,168 feet. This record was bettered on 18 September by Roland Rohlf, whose altimeter registered 34,610 feet. Lieut.-Col. Leonhard H. Drennan, of the Air Service, flew from Boston, Mass., to Hazelhurst Field, Long Island, in 83 minutes, a distance of 175 miles, in a DeHaviland four machine. Col. Davenport Johnson and Lieut. H. S. Ormsbee (pilot) of the Air

Service flew from Chicago to Selfridge Field, Mich., a distance of 250 miles in 140 minutes, in a DeHaviland four. And in this same year (1919) is realized the ultimate dream of the aviator, flight across the Atlantic Ocean. Under the supervision of the United States navy the naval seaplane NC-4 (piloted by Lieutenant Read) made a flight from Rockaway to Plymouth, England, a distance of 3,926 nautical miles, in 55h. 33m. actual flying time, averaging 70.80 miles an hour while in flight. The entire course and dates are as follows: Rockaway-Chatham (forced to land) 8 May; Chatham-Halifax, 14 May; Halifax-Trepassey, 15 May; Trepassey-Horta (Azores), 1,200 nautical miles, 16-17 May; Horta-Ponta Delgada, 20 May; Ponta Delgada-Lisbon, 27 May; Lisbon-Mondego River, 30 May; Mondego River-Ferrol, 30 May; Ferrol-Plymouth, 31 May. Still more remarkable was the non-stop flight across the Atlantic Ocean, from Saint Johns, Newfoundland, to Clifden, Ireland, made by Capt. John Alcock and Lieut. Arthur W. Brown, 14-15 June, in an English Vickers-Vimy bomber biplane. They made the distance, 14-15 June, 1,980 miles, in 16 hours 12 minutes, at 120 miles per hour.

RAILROAD SPEEDS.

As railroading is not a sport, judges have not verified the records we have of the fastest attainments of locomotives and trains. The following are generally accepted as the highest speeds on rails:

Egg Harbor to Brigantine Junction (Philadelphia and Reading), 4.8 miles, in 2m. 30s., averaging 115.20 miles per hour (1904). Crittenden run of "Empire State Express" (1893) of New York Central and Hudson River, one mile in 32s., averaging 112.5 miles per hour. The Plant system is said to have run, in 1901, a train from Fleming to Jacksonville, a distance of five miles, in 2m. 30s., an average of 120 miles per hour. A trial test of steam vs. electric locomotives was made, in 1907, by the Pennsylvania Railroad at Clayton, N. J.; the track was seven-mile curve specially constructed, and speeds were: steam, 93.6 miles per hour against 90 miles electric. Records in long distances are: Eckley to Wray on Burlington Route, in 1902, covering 14.8 miles in 9m., an average of 98.7 miles per hour. Paddington to Bristol, England, 118.5 miles in 1h. 24m., or average 84.6 miles per hour on the Great Western Line in 1904. In 1897 the "Black Diamond Express" (Lehigh Valley Railroad) ran from Alpine, N. Y., to Geneva Junction, N. Y., 43.96 miles, in 33 minutes, an average of 80 miles per hour.

AUTOMOBILE RACES.

Vanderbilt Cup.

Date	Car	Driver	Place	Miles	Average
1912.....	Mercedes.....	De Palma.....	Milwaukee.....	299.54	68.97

1915.....	Stutz.....	Anderson.....	Chicago.....	301.44	77.256

In 1918 a number of races showed the following records: Brooklyn, N. Y., 100 miles, in 50m. 21s. by De Palma in a Packard. Chicago, 100 miles, in 55m. 25s. by Chevrolet in a Frontenac.

In 1919 Ralph de Palma, at Sheepshead Bay in a Packard, made 50 miles in 26m. 23 1-5s. For other records see World's Records tables at end of this article.

BICYCLING RECORDS.

Owing to the European War no world championships have been competed for since 1913. Speed records are:

Professional Motor-Paced in Competition.—One mile by McLean in 1.09 1-5, 1903; two miles in 2.19 by McLean, 1903; 26 miles in 29.22 3-5 by Walthour, 1904; 30 miles in 33.52 3-5, by Walthour, 1904.

Motor-Paced Against Time.—One mile in 1.04 1-5 by M. Bedell, 1917; two miles in 2.09 4-5 by Duer, 1909; five miles in 5.18 2-5 by M. Bedell, 1917; 10 miles in 10.59 3-5 by M. Bedell, 1917.

Unpaced Against Time.—One mile in 1.51 by Goulet, 1912; two miles in 4.01 3-5 by Pye, 1910; five miles in 10.38 by Williams, 1909; 10 miles in 23.09 2-5 by Hamilton, 1898.

Amateur Unpaced Against Time.—One mile in 1.55 by Giles, 1908; two miles in 4.09 by Giles, 1908; five miles in 11.00 by Giles, 1908.

Six-Day Race Winners.—1913, Goulet and Fogler, 2,751 miles; 1914, Goulet and Grenda, 2,758.1 miles; 1915, Grenda and Hill, 2,770.8; 1917, Goulet and Magin, 2,473.4; 1918, Madden and Corry, 1,303.4; 1919, Goulet and Magin, 2,510.

Road Records.—American Amateur with Competition.—One mile in 2.02 by Surman, 1908; two miles in 4.56 1-5 by J. Steinert, 1911; five miles in 12.28 2-5 by J. B. Hawkins, 1908; 10 miles in 23.08 by Thomas Bello, 1915; 25 miles in 1.03.07 by Thomas Bello, 1915; 50 miles in 2.14.00 4-5 by Edwin Jensen, 1915; 100 miles in 5.06.12 by T. La Rossa, 1911; 150 miles in 8.26.27 by J. G. Kopsky, 1912.

MOTORCYCLE RACES.

Records will be found in World's Records section end of article.

ATHLETIC SPORTS.

The maintaining and enforcing of clear-cut amateur conditions surrounding the entries and contests of the various athletic clubs, and the elimination of professionals surreptitiously getting into the ranks, necessitated a unification of clubs and setting up of jurisdiction centred in some body. In England the Amateur Athletic Association (A. A. A.) was founded in 1880 at Oxford, confederating the legitimate clubs. After the New York Athletic Club for three years had managed the amateur championship meeting they had established and successfully carried on, the New York Athletic Club determined in 1879 to give up this management. The club had found the games profitable but the calls for the officers' time was too great in appeals as to decisions on athletic law, information as to the dates of the games, programs, entries, etc. So the New York Athletic Club decided to hand over the conduct of the championship games to a regularly organized asso-

ciation of athletic clubs. Such an association was formed under the title "National Association of Amateur Athletes of America." But abuses crept in and the good name of the amateur sports was endangered. This led to the determination to form a national amateur union of clubs under the title "Amateur Athletic Union of the United States," which was organized in 1888. Reliability of the records is the outcome. As George P. Meade well expresses present conditions: The rules of the records are "timed by at least three skilled timers, distances are accurately surveyed and are remeasured in case a claim for a record is to be made; strict rules are observed to prevent mistake or fraud at the start and finish, and unusual circumstances, such as favoring winds, are noted by judges and referee. Finally the performance is investigated by a committee of the national athletic board of the country in which the race was run, and every circumstance that might affect the validity of the record is discussed before the record is sanctioned. (These precautions apply only to amateur athletics)."

BOXING RECORDS.

Professional Champions. Heavyweights (over 158 lbs.): John L. Sullivan, 1890-92; James J. Corbett, 1892-97; Robert Fitzsimmons, 1897-99; James J. Jeffries, 1899-1910; Jack Johnson, 1910-15; Jess Willard, 1915-19; Jack Dempsey, 1919-. *Middleweights* (158 lbs.): Robert Fitzsimmons, 1890-97; Tommy Ryan, 1897-1907; Stanley Ketchel, 1907-08; Billy Papke and Stanley Ketchel, 1908; Stanley Ketchel, 1908-10; Frank Klaus, Mike Gibbons, Ed. McGoorty and George Chip all claim championship from 1911-13; Al McCoy, 1914-17; Mike O'Dowd, 1917-18. *Welterweights* (145 lbs.): Tommy Ryan, 1894-96; Kid McCoy, 1896-97; Billy Smith, 1898-1900; Rube Ferns, 1900; Matty Matthews and Rube Ferns, 1901; Joe Walcott, 1901-04; Dixie Kid, 1904-08; Kid Graves, 1914-16; Jack Britton, 1916; Ted (Kid) Lewis, 1917-18. *Lightweights* (133 lbs.): Jack McAuliffe, 1890-93; Kid Lavigne, 1893-99; Frank Erne, 1899-1902; Joe Gans, 1902-08; Battling Nelson, 1908-10; Ad Wolgast, 1910-12; Willie Ritchie, 1912-14; Freddy Welsh, 1914-17; Benny Leonard, 1917-18. *Featherweights* (122 lbs.): George Dixon, 1892-97; Solly Smith, 1897; Solly Smith and Dave Sullivan, 1898; George Dixon, 1898-1900; Terry McGovern, 1900-01; Young Corbett, 1901-04; Tommy Sullivan, 1904-08; Abe Attell, 1908-11; Johnny Kilbane, 1911-18. *Bantamweights* (116 lbs.): George Dixon, 1890-92; none recognized from 1892-94; Jimmy Barry, 1894-98; none recognized from 1898-1901; Harry Forbes, 1901-03; Frankie Neil, 1903-05; none recognized from 1905-07; Johnny Coulon, 1907-13; Kid Williams, 1914-15; Pete Herman, 1916-18. For earlier champions see under title PRIZE-FIGHTING.

Prize-Fighting. Amateur Champions in 1918, *A. A. U. National*: 108-pound class, Joe Wiles, Boston; 145-pound class, James Sullivan, New York; 158-pound class, Martin Burke, New Orleans; 115-pound class, James Tomasulo, New York; 175-pound class, John McMinimen, Camp Devens; 125-pound class, James Fruzetti, Brockton; 135-pound class, Thomas O'Malley, Philadelphia; heavyweight class,

Martin Burke, New Orleans. *Metropolitan Association A. A. U.*: 108-pound class, D. Kamins, Clark House A. A.; 115-pound class, James Tomasulo, Elizabeth Y. M. C. A.; 125-pound class, A. Schick, unattached; 135-pound class, S. Mosberg, unattached; 145-pound class, J. Sullivan, Union Settlement; 158-pound class, S. Lagonia, Bronx Athletic Club; 175-pound class, G. Schalk, unattached; heavy-weight class, G. Schalk, unattached. *New England A. A. U.*: 115-pound class, Bob Josephs, Boston; 158-pound class, Billy Rush, Boston Navy Yard; 108-pound class, Joe Willis, Chelsea; 125-pound class, Charles Parker, Boston; 135-pound class, Joe Melanson, Boston; 145-pound class, Al. Lacy, Chelsea; 175-pound class, Billy Rush, Boston Navy Yard.

BASEBALL RECORDS.

This most popular of American games suffered with the rest through the World War. And the "Work or Fight" regulations placed the professional league members, in 1918, among the "non-essential" classes of workers. The National, American and International leagues closed 2 Sept. 1918, the pennant winning clubs continuing the world series only. Boston won, defeating Chicago four games to one.

BILLIARDS AND POOL.

These are probably the most internationally popular indoor games. Already mentioned in the 16th century billiards has retained its hold among most civilized nations.

Best Billiard Record Runs. Professional: 312 at 18.2, Calvin Demarest, Chicago, 1910; 155 at 18.1, Willie Hoppe, Philadelphia, 1910; 246 at 18.2, Maurice Vignaux, Chicago, 1883; 303 at 14.1, Willie Hoppe, New York, 1914; 85 at straight cushion-caroms, F. C. Ives, Boston, 1906; 398, champion's game, Paris, 1882; 2,196 at English billiards, George Gray (Australian), at London, 1911. *Amateur*: 175 at 18.2, L. Lerolle, Paris, 1908; 202 at 14.2, Calvin Demarest, Chicago, 1908.

Best Record Averages. Professional: 135¼ at 18.2, Willie Hoppe, Chicago, 1914; 40 at 18.1, Jacob Schaefer, Chicago, 1898; 10 at straight cushion-caroms, J. Schaefer, New York, 1883; 37.97 at champion's game, G. F. Slosson, Paris, 1882; 52 at 14.1, George Sutton, Baltimore, 1914. *Amateur*: 57.14 at 14.2, Calvin Demarest, Chicago, 1908; 33.33 at 18.2, Lucien Lerolle, Paris, 1903.

Pool: under new rule, best run—74, Morton Phillips, Chicago, 1913; in amateur city championship—59, Alfredo de Oro, New York, 1913 (professional).

NATIONAL CHALLENGE CUP.

1913 True Blues, Paterson
1914 Bethlehem F. C., Bethlehem
1915 Scottish-Americans of Newark
1916 Bethlehem F. C.
1917 Fall River Rovers
1918 No games

INTERCOLLEGIATE LEAGUE.

1913 Harvard
1914 Pennsylvania
1915 Haverford
1916 Pennsylvania
1917 Pennsylvania
1918 Games canceled

YALE-HARVARD FOOTBALL.

1913 Harvard
1914 Harvard
1915 Harvard
1916 Yale
1917 No games
1918 No games

National Amateur Championships: Joseph Mayer, Philadelphia, 1913; Edward W. Gardner, Montclair, N. J., 1914; Joseph Mayor, Philadelphia, 1915; E. W. Gardner, 1916; Nathan Hall, Boston, 1917; Corwin Huston, Detroit, 1918.

TRAP SHOOTING RECORDS.

Recent winners of the Grand American Tournament are: W. E. Phillips, 1912; M. S. Hootman, Dayton, 1913; W. Henderson, Dayton, 1914; L. B. Clark, Chicago, 1915; J. F. Wolf, Saint Louis, 1916; C. H. Larson, Chicago, 1917; F. S. Tomlin, Chicago, 1918.

CHESS RECORDS.

This game is very ancient and ascribed to India, China, Persia and even Egypt. There was a chess club at Slaughter's coffee house, London, in 1747, and M. F. A. Danikin ("Philidor"), who died 1795, played three matches blindfolded at the Salopian. The London Chess Club was founded in 1807. Herr Paulsen (1861) played 10 games at once, winning five, three being drawn and one not played out. International Chess Congresses were started in 1851. Noted players of the 19th century were Howard Staunton, J. J. Lowen-

thal, J. H. Zukertort, etc. The World War greatly restricted activity in the game, Europe being entirely out of the game. J. R. Capablanca, of Havana, in 1918 showed his marvelous powers in 38 games played at the Manhattan Chess Club, winning 33, with 5 draws. The Manhattan Chess Club championship of 1918 was won by Oscar Chajes, 6-1, who also won at the Winter Meet of the New York State Association. In the International Tournament of 1918 Capablanca was the winner.

FOOTBALL RECORDS.

This is probably the second most popular sport in both the United States and England. Chester, England, had had a great annual football game up to the 16th century, when the match was discarded in favor of foot-races patronized by the city authorities. Eton, Rugby and Soccer rules have their advocates, but the latter style of play seems to be favored at present. In 1916 an all-American team of the United States Football Association went to Scandinavia where they won three games out of six, lost one and two were drawn. In 1917 the National Challenge Cup was won by the Fall River Rovers. Previous winners of this and other games were:

BASKETBALL RECORDS.

Intercollegiate League Winners: 1912, Columbia; 1913, Cornell; 1914, Cornell; 1915, Yale; 1916, Pennsylvania; 1917, Utah; 1918, Pennsylvania.

LAWN TENNIS RECORDS.

National Championship: 1913, M. E. McLoughlin; 1914, R. Norris Williams; 1915, Wm. M. Johnston; 1916, R. Norris Williams; 1917, no contest; 1918, Robert Lindley Murray. *Davis Cup Contests*: 1913, U. S. A.; 1914, Australasia; 1915, no contests during World War.

WRESTLING RECORDS.

Intercollegiate Championships (by points): 1912, Cornell; 1913, Cornell; 1914, Cornell; 1915, Cornell; 1916, Cornell; 1917, Cornell; 1918, Penn State.

Professional International Tournament: 1915, Zbyszko won final bout at New York City.

FENCING RECORDS.

One-hour unpaced record is 27.50 by Oscar Egg, 1914.

MOTORCYCLE RECORDS.

Professional: One mile in 36s.; two miles in 1m., 12 2/5s.; five miles in 3m., 6 4/5s.; 10 miles in 6m., 6 1/8s.; 25 miles in 16m., 27s.; all by Ray Seymour, 1912. 50 miles in 33m., 55 1/5s. by W. Humiston; 100 miles by Humiston; 200 miles in 4h., 5m., 54 2/5s., by H. Martin, 1909; 400 miles in 9h., 6m., 25 4/5s., by H. A. Collier, 1909. In 6 hours 294 miles 800 yards; 12 hours, 471 miles 784 yards. In continuous riding, A. T. Bedell did 1,153 1/2 miles in 24 hours, 1917.

Amateur one-mile in 55 4/5s., by C. Spencer, 1909, with standing start; Lon Claflin, 1912, did one mile in 38 4/5s., five miles in 3m., 18 4/5s., 10 miles in 6m., 42s. Fred Huyck did (1909) 25 miles in 20m., 54s. 100 miles was done by M. J. Graves, 1915, in 1h., 34m., 41s. 500 miles in 10h., 22m., 36s., by C. Spencer, 1909, who did 1,000 miles in 22h., 20m., 59s., same date.

MOTOR BOAT RACING RECORDS

1913. Philadelphia to Bermuda (734 miles) won by *Dream* in 87h., 25m. Bermuda to Brooklyn (680 miles) by *Tocsam II* in 70h., 27m., 39s. New York to Albany (235 miles) by *Blue Peter V* in 23h., 2m., 45s. International Harmsworth Trophy won at Isle of Wight by *Mapleleaf* at average speed 55.646 miles per hour. (No races till after the War.)

1916. The Lake George Cup Race winner, *Miss Minneapolis*, averaged in six one mile trials a speed of 61.08 statute miles per hour.

1917. New York City to Albany and return, 235 miles in 29h., 38m., 26s., by *Luella*. Miami to Palm Beach, Fla., 70 miles, in 1h., 47m., by *Raven III*. In the National One-Mile championship race, *Miss Detroit II* won. She did six one-mile dashes against time, averaging 61.72 miles per hour.

SKATING.

American amateur records: 50 yards, Robert McLean in 5s. (1914). 100 yards, Morris Wood in 9 3/5s. (1903). One mile, Morris Wood in 2m., 41 1/5s. (1904). One and one-half miles, L. Roe in 4m., 10s. (1910). Four miles, A. Schiebe in 12m., 4s. (1894). Five miles, B. Lamy in 14m., 55s. (1910). 1,000 metres, J. K. McCulloch in 1m., 47s. (1897). 1,500 metres, J. K. McCulloch in 2m., 40 4/5s. (1897). 5,000 metres, J. K. McCulloch in 9m., 25 2/5s. (1897).

World's amateur records: 500 metres in 43 7/10s.; 1,000 metres in 1m., 31 2/5s.; 1,500 metres in 2m., 19 1/2s.; 5,000 metres in 8m., 36 3/5s.; 10,000 metres in 17m., 22 6/10s. All by O. Mathiesen of Norway.

Professional records: 50 yards, S. D. See and C. B. Davidson in 6s. (1885). 100 yards, J. S. Johnson in 9 4/5s. (1893). 440 yards, J. S. Johnson in 31 3/4s. (1896). 600 yards, O. Rudd in 55 3/5s. (1893). One mile, Arthur Staff in 2m., 35s. (1916). One and one-half miles, J. Johnson in 4m., 28s. (1894). Two miles, J. Nilsson in 5m., 33 2/5s. (1900). Three miles, J. Nilsson in 8m., 41 1/5s. (1900). Four miles, J. Nilsson in 12m., 1/5s. (1897). Five miles, O. Rudd in 14m., 34s. (1896). 20 miles, A. D. Smith in 1h., 6m., 36 2/5s. (1894). 25 miles, John Karlson in 1h., 30m., 15s. (1916). 50 miles, J. F. Donohue in 3h., 15m., 59 2/5s. (1893). 100 miles, J. F. Donohue in 7h., 38 1/5s. (1893).

BOWLING.

World's records: Individual, open, three games, Roy Flagg, 270, 300, 300, average 290, 1906. Six games, Lee R. Johns, average 271 1/2, 1909. All events, Mortimer Lindsey, in nine games, average 225 6/9, 1912. Highest woman's score, Mrs. Nellie Lester, New York, 277, 1909. Two-men, open, Knox-Satterthwaite, Philadelphia, 1,445, 1912. Six games, Charles Schaefer, average 256 1/6, 1907.

SPORTS IN PLANTS, a term in biology denoting an individual which differs more or less markedly from the type or parent species; an aberrant form. It is distinguished from

"monstrosity" by its ability to transmit its aberrant character either sexually or asexually to offspring; whereas monstrosities properly so-called lack this power, their offspring, if any, reverting to the general type. The origin of sports has furnished much food for speculation, some biologists assuming that aberrations are freaks which nature destroys, while others declare that the transmutation of species is dependent upon them through the processes of natural selection of the adaptive ones. If the term is to be used as an approximate synonym of monstrosity the first hypothesis is probably true; but if used in its broadest sense the latter is more nearly correct. The matter hinges mainly upon the extent of observation; for, while sports among undomesticated animals are comparatively rare, they are numerous among uncultivated plants, but have been commonly overlooked because biologists have been more awake to the animal than the plant. Each leaf-bud of a plant is capable of producing leaves and branches which differ from those produced by any other bud, and every flower-bud may produce a flower unlike any of its fellows; nay, further, the individual seeds which follow any flower in a single fruit may produce plants unlike one another in many respects and also unlike the parent. But unless these departures are striking enough to attract the attention of the ordinary observer as distinct they are unnoted and hence not calculated upon; hence the popular opinion that sports appear "suddenly," since only the remarkable cases are observed.

They can be no doubt that sports result from unusual or complex stimuli or unaccountable refrangibility of vegetative force, and for these reasons may be, usually are, unstable when normal conditions are again operative. However, this does not oppose but it rather enforces the statement that sports result from the same causes as underlie all variation in the plant kingdom, bud-variation being one of the most important and significant phenomena of plantlife. But though the causes are usually unknown in plants and vertebrate animals, sports have been produced artificially with diverse lepidopterous insects by varying the humidity, dryness and temperature of the air during the process of growth or pupation. The crossing of the sports with the type-species does not usually result in an intermediate form but in two main groups, in one of which the offspring resemble the male parent and in the other the female.

From a practical standpoint, selection and breeding of sports has long been widely employed. Among domestic animals one of the most striking instances is that of Ancon or otter sheep, the ancestor of which was a long-bodied, crooked-legged freak which was bred to sheep of normal character. Only the individuals which resembled the aberrant parent were used for subsequent breeding. With domesticated plants the practice of breeding from the sports is still more striking, because it can be practised either sexually or asexually. The initial sport may appear as a seedling or as a "bud-variation." In the former case the gardener usually propagates by means of seed, rigorously discarding all specimens that depart unfavorably from the apparent intent of the primal sport, and carefully saving those speci-

mens that approximate or accentuate the characters. If the sport is a bud-variation the gardener usually propagates it by means of cuttings, practising a careful suppression of individuals which seem to retrogress and selecting desirable ones for further propagation, as in the former case. It may seem expedient to practise asexual methods with a plant produced sexually or vice-versa; in each case, however, the after-selection is imperative. Some bud-varieties fail to "come true" even from cuttings, and failure in this respect is common among seed sports. Bud-variation and seed-variation are the same kind since the same means of improvement can be used in each case.

Far from being comparatively rare, sports are very common among cultivated plants, almost every species of importance furnishing instances. Among well-known bud-sports: the purple or copper beech, purple-leaved plums, and many weeping, variegated and cut-leaved trees and shrubs, are familiar examples. The *perle des jardins* rose has given rise to several commercially important bud-varieties. The moss-roses are bud-sports. The "mixing" of potatoes in the hill is also well known. Among plants propagated by seeds instances are legion — tomatoes, cabbage, corn, parsley, onions and a host of garden flowers. Probably the most striking instance of a plant producing both bud-sports and seed-sports of value is the peach. Occasionally a seed will produce a smooth-skinned fruit popularly called a nectarine, which in turn may produce either a nectarine or a peach. Certain branches of the peach tree may produce nectarines and vice-versa. Russet apples are sometimes seen upon greening trees. The sports may occur in any part of the parent plant — roots, tubers, rhizomes, stems, flowers, leaves, seeds and even buds upon the stem or the roots.

Another practical application of the tendency to sport among plants is the grafting of fruit trees with scions taken from the "bearing wood" of specially prolific or precocious trees of any particular variety. Such scions usually commence to bear earlier, or produce more regularly, or both, than scions taken from shaded portions of the same parent trees or from unproductive individuals.

One of the common troubles with sports is self-sterility. This is scarcely important except with fruit trees where, if large blocks of one kind of tree are planted remote from other varieties that blossom at the same time, little or no fruit will be set. See paragraph *Varieties* under title *APPLE*.

Sports are to be distinguished from reversions in which the individual seems to hark back to the general form of its more or less distant ancestors. They must also be separated from cases of atavism (q.v.) in which the progeny exhibit a character not typical of their race, species or genus but characteristic of an allied ancestral race. Instances of reversion (q.v.) are the loss of the bulbous root of turnips and the "head" of cabbage which "run Wild"; of atavism, the occasional appearance of several-toed horses, whose feet somewhat resemble the three-toed foot of the horse of Tertiary time. See *BREEDING*; *BUD*; *HEREDITY*; *HYBRIDITY*; *NATURAL SELECTION*; *VARIATION*, and consult the authorities cited under them.

SPOT, a fish. See *GOODY*.

SPOTSWOOD, spòts'wùd, **Alexander**, American colonial governor: b. Tangier, Africa, 1676; d. Annapolis, Md., 7 June 1740. He entered the English army in early youth, fought at the battle of Blenheim, was deputy quartermaster-general under the Duke of Marlborough and in 1710 was appointed governor of Virginia. His administration was one of great benefit to the colony, he was the bearer of the writ of habeas corpus, a fact which gained for him the favorable attention of the colony, and his popularity was for a long time unbroken. He greatly assisted the William and Mary College, concluded a treaty with the Six Nations in 1722 which secured for the colonists the territory east of the Blue Ridge, south of the Potomac, and originated the act to make tobacco notes a medium of purchase, introduced various beneficial measures into the colony. His aim was invariably the good of the colony, but his haughtiness won for him in time enemies, and the controversy which arose over church patronage, which he held to be a privilege of his office, enabled his opponents to gain his removal from office in 1722. He continued his residence in Virginia, served as deputy postmaster-general in 1730-39 and greatly improved mail facilities. He fostered the iron industry, endeavored to promote vine-culture and otherwise evinced an undiminished interest in the colony. In 1740 he was appointed major-general to command an expedition to the West Indies, but died just previous to embarking. His letters were purchased by the Virginia Historical Society in 1882 and published in their collection as 'The Official Letters of Alexander Spotswood, Lieutenant-Governor of Virginia in 1710-1722' (1882-85).

SPOTSWOOD, or **SPOTISWOOD**, spòt'-is-wùd, **John**, Scottish ecclesiastic: b. in the parish of Mid-Calder, Midlothian, 1565; d. London, 26 Nov. 1639. He studied at the University of Glasgow, and at 18 became assistant to his father as parson of Calder. At the outset he supported the Presbyterian party, but in 1601, when the Earl of Lennox was sent as Ambassador to France, Spotswood accompanied him as chaplain and "made no scruple to go in to mass." On his return he was complained of to the General Assembly, but through the influence of the court escaped with merely a reprimand. He became a favorite at court, and in 1603, when King James set out for England, was one of the five Scottish clergymen selected to accompany him. In the course of the journey news arrived of the death of the archbishop of Glasgow, and Spotswood was immediately appointed his successor, and in consequence returned to Scotland, but was not consecrated till 1610. In 1615 he exchanged Glasgow for the metropolitan see of Saint Andrews and became primate of Scotland. In 1618 he presided over the General Assembly at Perth, and succeeded in carrying the five points of ecclesiastical discipline known as the Perth Articles. He continued to enjoy royal favor under Charles I, whom he crowned in the abbey church of Holyrood in 1633, and a little later he was made chancellor of Scotland. But by his harsh procedure against Lord Balmerino contributed greatly to inflame the opposition to episcopal government, which now became general among all ranks, and finally led to its overthrow. In

1638, at the assembly held at Glasgow, he was deposed, excommunicated and declared infamous. He saved himself by flight, and took up his residence in London, where he died. He is the author of a 'History of the Church of Scotland' (1655), commencing at 203 and continued to the end of the reign of James VI.

SPOTTED FEVER, cerebro-spinal meningitis. (See MENINGITIS). Spotted fever is a term also applied to a form of typhus fever (q.v.).

SPOTTED SANDPIPER. See SANDPIPER.

SPOTTISWOODE, spõt'is-wüd, William, English mathematician and physicist: b. London, 11 Jan. 1825; d. 27 June 1883. He was educated at Balliol College, Oxford, and in 1846 became manager of his father's printing establishment, the well-known house of Eyre and Spottiswoode. He was the author of 'A Tarantasse Journey through Eastern Russia' (1857); 'Meditationes Analyticae' (1847); 'Elementary Theorems relating to Determinants' (1851); 'The Polarization of Light' (1874), etc. He was president of the London Mathematical Society (1870-72), of the British Association (1878), and of the Royal Society (1878). In mathematics he is chiefly distinguished as one of the first to make extensive use of the symmetrical determinant notation, and as the author of a series of papers in the 'Philosophical Transactions' of 1862 and the following years on the contact of curves and surfaces. In physics he devoted himself mainly to the study of polarized light and electrical discharge through rarefied gases.

SPOTTSYLVANIA COURT HOUSE, Battles of. The battle of the Wilderness (q.v.) was fought 5 and 6 May 1864, and a reconnaissance made by General Birney's division down the Orange plank road, on the morning of the 7th, developed the fact that the Confederates had fallen back to their entrenched lines, with pickets to the front, covering a part of the battlefield. "From this," says General Grant, "it was evident to my mind that the two days' fighting had satisfied him (Lee) of his inability to further maintain the contest in the open field, notwithstanding his advantage of position, and that he would await an attack behind his works. I, therefore, determined to push on and put my whole force between him and Richmond, and orders were at once issued for a movement by his right flank." The first objective was Spottsylvania Court House, 15 miles southeast of the Wilderness field, which, by a night march it was proposed to reach early on the morning of the 8th. As a preliminary to the movement Sheridan's cavalry was to seize Todd's Tavern, on the Brock road, midway between the Wilderness field and Spottsylvania Court House, and hold the place and the roads crossing Po River. This was done on the 7th, the Confederate cavalry being driven from the place, Wade Hampton's division retreating south to Corbin's bridge over the Po, and Fitzhugh Lee's eastward on the Brock road toward the Court House. (See TODD'S TAVERN, ENGAGEMENT AT). At 3 p.m. the trains began their movement toward Chancellorsville and Piney Grove Church; Warren's Fifth corps started after dark and, marching on the Brock road, along the rear of Hancock's Second corps,

arrived at Todd's Tavern at 3 a.m. of the 8th, much impeded and delayed in its march by the mounted provost guard of the army which immediately preceded it; Sedgwick's Sixth corps followed, marching eastward to Chancellorsville, then southward to connect with Warren; and Burnside's Ninth corps followed Sedgwick. Hancock's Second corps did not march until daylight when it moved to the left on the Brock road to Todd's Tavern, which it reached at 9 a.m. of the 8th, and entrenched. When Warren arrived at Todd's Tavern he found Merritt's cavalry division engaged with that of Fitzhugh Lee. At 6 a.m. Merritt was withdrawn and Robinson's division of Warren's corps took its place and, slowly driving back Lee's cavalry, had reached open ground one and one-half miles from the Court House, when from a piece of wood 200 to 300 yards in front it received a heavy musketry and artillery fire, which severely wounded Robinson, and so staggered his division that it fell back to the woods in its rear. Robinson had encountered two brigades of R. H. Anderson's corps, the advance of Lee's army, which had beaten Grant in the race for Spottsylvania Court House. Lee had divined Grant's intention and, on the 7th, had cut a military road through the forest from the Orange plank road to the highway by Shady Grove Church, thence eastward to the Court House; and being informed by Stuart, late in the day, that Grant's trains were in motion southward, that night he gave orders for the movement of his army to the Court House, on roads nearly parallel to the Union line of march, and but a mile from the Brock road. Gen. R. H. Anderson, who commanded Longstreet's corps, had been ordered to move on the morning of the 8th, but being much troubled by the fire and suffocating smoke in the Wilderness woods, concluded to avoid it, set out at 11 p.m. of the 7th and, marching all night, arrived near the Court House at 8 o'clock next morning. There, finding Lee's cavalry engaged with Warren's infantry, he marched part of his corps to Lee's support, and two brigades marched on to the Court House and occupied it, Wilson's cavalry division, that had been sent by Sheridan to seize it, and that had been in possession two hours, withdrawing. Lee's cavalry withdrew as Anderson came up, and Anderson took up the fight with Warren. Griffin's division of Warren's corps, which had advanced on Robinson's right, was repulsed, and both fell back upon Crawford's and Cutler's divisions, which had now reached the front. Cutler advanced and drove the Confederates from Griffin's right, and Warren threw up intrenchments from 200 to 400 yards from those of the enemy. It was now about noon. About 1 p.m. Sedgwick came up, under Meade's order to support Warren in an assault upon the Confederate position, the right of which rested on the Brock road. It was late in the day when the assault was made. Penrose's New Jersey brigade of the Sixth corps charging over open ground was repulsed by the right of Anderson's corps. A little later Crawford's division of Warren's corps went forward, passed the right of Anderson and struck Rodes' division of Ewell's corps, which was going into position on Anderson's right. Rodes, taken at a disadvantage, was driven back some distance, but rallied and drove Craw-

ford back to his intrenchments. Ewell's entire corps came up during the evening and formed on Anderson's right. The Union loss during the day was about 1,300.

A. P. Hill's corps, under command of General Early, came up on the morning of the 9th, and Lee established his lines covering Spottsylvania Court House, with Anderson's corps on the left, resting on Po River, Ewell's corps in the centre and Hill's on the right, covering the Fredericksburg road. The line was 8 to 10 miles long, and the greater part of it ran through woods tangled with undergrowth, or on the edge of them, with slashings and abatis in front. It was everywhere strongly intrenched and well planted with artillery. During the 9th Lee was employed in rectifying and strengthening this line, and Grant in examining and developing it, and also in readjusting his own lines. Skirmishing was sharp on both sides, and early in the morning General Sedgwick, commanding the Sixth corps, was killed. General Wright succeeded to the command of the corps. Early in the day Burnside moved across from the Plank road to the Fredericksburg road, at the crossing of Ny River, east of the Court House, and threw one of his divisions across the river, which encountered infantry and some dismounted cavalry. Hancock moved east from Todd's Tavern to the right of Warren and intrenched, overlooking Po River. Sheridan cut loose from the army and started from Todd's Tavern on his Richmond raid. Burnside had reported to Grant that in his movement on the 9th he had met the enemy east of the Court House and judged from indications in his front that Lee was meditating a movement north toward Fredericksburg, upon which Grant ordered Hancock to make a movement on the 10th on Lee's left, across the east and west bends of Po River. This movement led to the engagement on Po River (q.v.). While this battle was in progress Warren was engaged in feeling the Confederate lines in his front preparatory to an assault and Gibbon's division was withdrawn from Hancock and placed on Warren's right and for the time under his orders. At 11 A.M. Gibbon advanced with two brigades, met an obstinate resistance from Fields' division and was compelled to fall back with much loss. Warren followed with two of his own divisions, with a view to gain ground for the formation of a column of assault, and was repulsed by Fields, but he had gained information of Fields' position which induced him to report to Meade that a general assault would be successful. Hancock had been designated to make the assault at 5 P.M. with the Fifth and Sixth corps and part of his own, but he was engaged at Po River, and at 3.45 P.M. Meade directed Warren to make the assault, which was done with Crawford's and Cutler's divisions of the Fifth corps and Webb's and Carroll's brigades of the Second. The assault fell upon Fields' division and failed, Warren being repulsed with heavy loss, including General Rice killed. General Hancock returned from Po River at 5.30 P.M., just before the close of Warren's assault, and at 7 P.M. made another assault with Birney's and Gibbon's divisions. This assault fell on Geo. T. Anderson's brigade and Gregg's Texas brigade, both of Fields' division. Some of the

assaulting troops gained the works held by the Texas brigade and went over them, pushing back the Texans; but a flank fire of Anderson's brigade drove them out and the attack was repulsed, many dead and wounded being left inside the works. The assaulting column fell back in some disorder, the men demoralized by the fruitless work.

At about the same hour General Wright, on the left of Warren, made an assault. He had found what he deemed to be a vulnerable place to a vigorous attack. It was on the west face of the noted salient, held by Rodes' division of Ewell's corps. Upton's brigade of the Sixth corps, reinforced by four regiments of Neills, was to make the assault, supported on the left by Mott's division of the Second corps, which was to assault on its own front at 5 P.M. Upton formed in four lines, and the batteries opened a direct and enfilading fire, which ceased only when Upton charged from the woods, and under a terrible front and flank fire, went over the Confederate works, broke Doles' brigade and part of Daniel's, captured many prisoners, and pushed on to a second line of works upon which he planted his colors, and captured a four-gun battery. He had broken the Confederate line to the length of a division; but Mott had failed in his allotted task of supporting him on the left; and recovering from their surprise and temporary disaster, the Confederates threw two brigades in his front; Daniels, R. D. Johnston's, J. A. Walker's and Steuart's brigades fell upon both flanks; and Upton was ordered to withdraw, which he did under cover of the darkness. He had lost about 1,000 men, many of whom were left dead and wounded inside the Confederate works. He was obliged to abandon the captured battery, but he carried back with him 1,200 prisoners and several stands of colors. Farther to the left Burnside made a reconnaissance toward Spottsylvania Court House, and had a spirited engagement, driving back the enemy close to the Fredericksburg road and intrenching a part of his line, as he reports, within a quarter of a mile of the Court House. In this engagement General Stevenson, one of his division commanders, was killed. During the day of the 10th the Union forces engaged numbered about 38,000; the losses were about 4,200 killed and wounded; but few were missing. The estimated Confederate loss was 2,000 killed and wounded.

On the morning of the 11th Grant reported to Halleck that in the six days' fighting since crossing the Rapidan he had lost 11 general officers and probably 20,000 men; renewed his call for reinforcements, which he hoped would be sent as soon as possible and in great numbers; and assured Halleck that he meant to fight it out on that line if it took all summer. Finding that the Confederate left was so well guarded, he made arrangements to attack the centre at a salient of the line. General Wright was directed to extend his left, concentrate on that wing and he prepared to co-operate with Hancock in an assault. Hancock, with the Second corps, was to pass to the left of Wright during the night and assault the salient at daylight. Warren's Fifth corps was to assault the works in his front to keep the Confederates in them, and on the extreme left Burnside was to lead the Ninth corps in an assault. The day was very stormy and disagreeable, and no

serious fighting took place, though there was heavy skirmishing along the entire line, in which the artillery occasionally took part. Wright extended his lines during the afternoon. The two divisions of Barlow and Birney of Hancock's corps started at 10 P.M., and at midnight reached the Brown House, where they found Mott's division; and passing over the intrenchments, and as near to the picket line of the enemy as possible, they began the formation of the column of assault. Barlow's division was formed across a clearing in two lines of masses, each regiment being doubled on the centre. Brooke's and Miles' brigades constituted the first line, and Smyth and Brown the second. Birney's division formed on Barlow's right, in two deployed lines. Mott formed in rear of Birney, and Gibbon's division was placed in reserve. It was nearly daylight when these preparations were completed, and the column formed within 1,200 yards of the Confederate line.

The Battle of the Salient.—The point to be assailed was where Lee's intrenchments had been carried northward to enclose a space about a mile in length and half a mile in width, of the general shape of an acorn: the Confederates called it the "Mule-Shoe." Taken together, the faces of the salient or "Mule-Shoe" covered about two and one-quarter miles in length, and were occupied mainly by Ewell's corps, Edward Johnson's division holding the apex or east angle of the works, and Rodes' division the west angle and face. To provide against contingencies, a second line had been laid off and partly constructed some distance in rear, so as to cut off the salient at its base. In rear of this line was Gordon's division as a reserve. On Ewell's right was A. P. Hill's corps; on his left was Longstreet's, commanded by R. H. Anderson. General Lee had detected some movements that indicated a withdrawal from the front of Anderson's corps and, under the impression that Grant had begun another flanking movement, late in the day he ordered the withdrawal of all the artillery in the left and centre, which was difficult of access, that it should be done before it was entirely dark and that everything should be in readiness to move at any moment. Under this order Ewell's chief of artillery removed all but two batteries from the line of Edward Johnson's division. During the night Johnson discovered that the Union troops were massing in his front; and, convinced that he would be attacked in the morning, he asked Ewell for the immediate return of the artillery. The men in the trenches were on the alert, when at dawn on the morning of the 12th they saw a dense column emerge from the woods half a mile in front of the salient and rush to the attack. Johnson says: "They came on in great disorder, with a narrow front, extending back as far as I could see." The charging column was Barlow's division, led by the brigades of Brooke and Miles. It had been ordered to make the assault at 4 o'clock, but owing to a heavy fog it was not sufficiently light to enable objects to be clearly discerned until 4.30, when the order to charge was given. Birney, on the right, met difficulty in the rough ground over which he moved, but kept nearly abreast of Barlow's line. When the Confederate works were seen a wild cheer was given; Brooke and Miles tore down the

abatis, and in the face of a deadly fire sprang over the intrenchments, and a desperate hand-to-hand encounter ensued; Birney came up on the right; the battalion of Confederate artillery that had been withdrawn came back just in time to have its horses and cannoneers shot down before a gun could be fired; and in a very short time nearly a mile of the works had been carried. General Johnson himself and General Steuart, 20 guns, 30 colors and nearly 3,000 men were captured. With scarcely a halt Barlow and Birney swept on for nearly half a mile; then, thoroughly disorganized, they were brought to a stand before another line of works, held by Gen. J. B. Gordon's division and Lane's brigade of Hill's corps. As Gordon was about to charge, General Lee rode up and joined him, evidently intending to go forward with him. Gordon remonstrated, the men cried, "General Lee to the rear!" and one of them seized the general's bridle and led his horse to the rear, and Gordon's men went forward and attacked the Union lines in rear of the captured works. After a fierce struggle in the pine woods the Union troops, piled in one upon another, six or eight lines deep, were forced back out of the works but held the outer side of them. The Sixth corps, coming up, took post on the right of the Second, occupying the line from the west angle southward; Mott's division joined the Sixth corps at that angle; Birney's division came next on the left; then Gibbon's; then Barlow's. All set at work to turn the captured intrenchments. There was great confusion in the intermingling of commands on a narrow front, and the Confederates now made most determined efforts to recover their intrenchments. Anderson sent troops from the left, three brigades of Hill's corps came from the right, and for the distance of nearly a mile, amid a cold, drenching rain, the combatants engaged in a desperate struggle across the breastworks. General Walker, the historian of the Second corps, says: "They fired directly into each other's faces; bayonet thrusts were given over the intrenchments; men even grappled with their antagonists across the piles of logs and pulled them over, to be stabbed or carried to the rear as prisoners. General Hancock had, as soon as the first success was achieved, brought up some of his guns to within 300 yards of the captured works, and these were now pouring solid shot and shell over the heads of our troops, into the space crowded with the Confederate brigades; he even ran a section of Brown's Rhode Island, and a section of Gibbs' Fifth United States, up to the breastworks; and though the muzzles protruded into the very faces of the charging Confederates, the begrimed cannoneers for a time continued to pour canister into the woods and over the open ground on the west of the McCod house. The contest had settled down to a struggle for the recovery of the apex of the salient between the east and the west angle. . . . Never before since the discovery of gunpowder, had such a mass of lead been hurled into a space so narrow as that which now embraced the scene of combat. Large standing trees were literally cut off and brought to the ground by infantry-fire alone. If any comparison can be made between the sections involved in that desperate contest, the fiercest and deadliest fighting took place at the west angle, ever afterward known as 'The

Bloody Angle.' Here Wright's Sixth corps had taken post on coming up at 6 o'clock. . . . All day long the bloody work went on, and still the men of the North and of the South were not gorged with slaughter. The trenches had more than once to be cleared of the dead, to give the living a place to stand. All day long, and even into the night, the battle lasted, for it was not till 12 o'clock, nearly 20 hours after the command 'Forward' had been given to the column at the Brown House, that the firing died down, and the Confederates, relinquishing their purpose to retake the captured works, began in the darkness to construct a new line to cut off the salient." During the day diversions were made on both sides to relieve the tremendous pressure in the centre. On the right of the Sixth corps, Warren, with a part of the Fifth, made an attack upon Anderson's corps and was repulsed with a loss of over 1,000 men. On Hancock's left Burnside's Ninth corps made an assault, and after lodging the head of column of Potter's division inside of Hill's works, it was attacked in flank and driven back with heavy loss. Later in the day General Early, commanding Hill's corps, advanced from his works to strike Burnside in flank, Burnside was met in motion and driven back to his works, and Early returned to his own lines. The Union forces engaged on the 12th numbered about 66,000 men, of whom 6,020 were killed and wounded, and 800 missing. The records do not show the number of Confederates engaged, nor their losses, but it is estimated that their total loss was between 9,000 and 10,000, of whom about 4,000 were captured.

On the morning of the 13th it was ascertained that the Confederates, failing to recover their lost intrenchments, had fallen back, and Colonel Carroll, with a brigade of the Second corps, went forward to reconnoiter, found them strongly intrenched on a new line at the base of the salient and after a sharp engagement withdrew. Dispositions were now made to turn Lee's right flank, and during the night of the 13th the Fifth corps, followed by the Sixth, moved over to the Fredericksburg road. The 14th was occupied in getting the two corps in position. The Confederates were found strongly intrenched on the Fredericksburg road in front of Spottsylvania Court House, and an attack was deemed inexpedient. During the day the Confederates attacked Upton's brigade of the Sixth corps, and compelled it to fall back from an advanced position, but the ground was immediately retaken by a brigade from the Fifth and one from the Sixth corps. When Lee saw that the Fifth corps had moved away from Anderson's front, Anderson's corps was shifted from the left to the extreme right, beyond the Fredericksburg road, and extended the line to Po River. Ewell still held the works in rear of the bloody salient. From the 12th to the 18th Grant was employed in constant reconnoitering and skirmishing, developing Lee's position and ascertaining if he could find a weak point in it; also in establishing a base at Aquia Creek, sending the sick and wounded there, drawing necessary supplies and awaiting the arrival of reinforcements from Washington to fill his depleted ranks. Early in the morning of the 18th the Second corps, supported by the Sixth corps on the right and Burnside's Ninth corps on the left, Warren assist-

ing with his heavy artillery, made an attempt to force the lines held by Ewell's corps, at the only point where former efforts had met with even partial success. It was a failure. Under the fire of 29 guns of Carter's battalion, which swept all the approaches to Ewell's line, the attacking force was driven back before it came well within reach of musketry, with a loss of over 2,000 killed and wounded. Grant gave up further effort; deeming it impracticable to break Lee's lines at Spottsylvania Court House, he issued orders on the 18th with a view to a movement to the North Anna to begin at 12 o'clock on the night of the 19th. In pursuance to this plan, on the 19th the Second and Ninth corps were moved to the left, the Ninth corps taking position on the left of the Sixth, with the Second in reserve. Late in the afternoon Ewell's corps attempted a flank march around Grant's left to ascertain the extent of his movement and get possession of the Fredericksburg road. He was met by Tyler's division of new troops, who, being reinforced by Crawford's division of the Fifth corps and Birney's of the Second, after a severe engagement lasting until dark, drove Ewell back. Some of Ewell's forces, pushing to the rear on the Fredericksburg road, met Ferrero's division of colored troops, by whom they were repulsed. Ewell's loss during the day was about 900. Grant reports his own loss as 196 killed, 1,090 wounded and 249 missing. Ewell's attack delayed Grant's march for the North Anna 24 hours. On the night of the 20th the Second corps and a small force of cavalry under General Torbert were pushed through Bowling Green to Milford, followed on the three succeeding days by the rest of the army. Lee followed, and the lines around Spottsylvania Court House were deserted. The entire losses of the Union army around Spottsylvania Court House from May 8 to 19 inclusive are estimated by General Humphreys as 15,722 killed and wounded, and 2,001 missing, an aggregate of 17,723. The Confederate losses are not known, but were very severe. Consult 'Official Records' (Vol. XXXVI); Humphreys, A. A., 'The Virginia Campaign of 1864-65' (New York 1883); Walker, F. A., 'History of the Second Army Corps' (ib. 1886); Powell, W. H., 'History of the Fifth Army Corps' (ib. 1896); Penny-packer, 'Life of General Meade'; Grant, U. S., 'Personal Memoirs' (Vol. II, New York 1885: 86); Early, J. B., 'The Last Year of the War for Independence' (ib. 1867); Lee, F., 'The Life of General R. E. Lee' (ib. 1894); Long, A. L., 'Life of General Lee' (ib. 1886); Gordon, G. H., 'A War Diary of Events in the War of the Great Rebellion' (Boston 1882); The Century Company, 'Battles and Leaders of the Civil War' (Vol. IV, New York 1887-88).

SPOUTING HORNS. Wave-cut caves along shore lines sometimes extend back some distance from the face of the cliff and by reason of a fracture or joint in the rock open up to the surface of the ground through a deep pit or well. During storms these frequently spout foam and water which has been driven into the cave by the waves. Such an opening is called a spouting horn or blowhole.

SPRAGUE, spräg, Austin Velorous Mil-
ton, American inventor: b. Rochester, N. Y.,
28 May 1840. He received special instruction

in law, medicine and engineering, and in 1865 went to the Pennsylvania oil-fields where he engaged in perfecting methods of improved oil production. The frequent explosion of boilers, caused by the use of the brackish water of the Allegheny River, suggested to him a plan for raising the water of the river to a reservoir whence it could be supplied to the boilers. He successfully executed his plan, overcoming the difficulty caused by an elevation of 740 feet in a distance of $2\frac{1}{2}$ miles. He has invented various household articles, improvements in laundry machinery, disinfectors, thermaerotherapeutic apparatus, introduced steam for the sterilization of surgical instruments and dressings in 1890, began experiments in 1891 with hot dry air for therapeutical purposes, since generally adopted, and introduced the use of steam for the disinfection of textile fabrics in 1899.

SPRAGUE, Frank Julian, American electrical engineer and inventor: b. Milford, Conn., 25 July 1857. While at high school in North Adams, Mass., he won competitive appointment to United States Naval Academy, from which he graduated with honors in 1878. He then became interested in electrical inventions and took a special course in physics under the late Admiral Sampson. Shortly after graduation he started on a tour of duty around the world, and was correspondent of the *Boston Herald* while General Grant was on the flagship of the Asiatic squadron. In 1882 he was appointed a member of the jury of awards at the Crystal Palace electrical exhibition, where he conducted all the tests on dynamo-electric machinery, electric lights and gas engines, his report being published in full by the Navy Department. In 1883 he passed examination for promotion, then obtained a year's leave, resigned and became assistant to Thomas A. Edison; a year later parted company with Mr. Edison and formed the Sprague Electric Railway and Motor Company, which, with his newly invented constant speed electric motor, began active exploitation for industrial purposes. Began inventions in electric railways in the early '80s, and conducted extensive experiments on the New York Elevated Railway in 1886. Is generally recognized as the pioneer of the modern trolley road, the first important installation of which was made by him at Richmond, Va., in 1887-88. (See *TRACTION, ELECTRIC*). In 1887 he invented the "multiple unit" system of electric train operation, by which several cars in a train are independently equipped, but all are under common control from several points. Has been an active exponent of underground electric traction. He was awarded a gold medal at the Paris Exhibition in 1889, the Elliot Cresson medal by the Franklin Institute in 1904, and the grand prize by the Louisiana Purchase Exposition for his inventions and developments in electric railways; also the Edison Medal, in 1910, for "inventive achievement in electrical science, engineering and arts." He was a member of the electrical commission which had charge of the electrification of the New York Central Railroad terminals, and coinventor of its protected third rail; also member of the commission which investigated the possibilities of electrification of the Sierra Division of the Southern Pacific Company and was primarily responsible for the use of high potential direct current in

railway work. He was chairman of committees on electricity and ship construction of the United States Naval Consulting Board; president of the Sprague Development Corporation and the Sprague Safety Control and Signal Corporation and inventor of system of automatic braking control of trains. He has written many scientific papers on electric motor and railways and kindred subjects.

SPRAGUE, Homer Baxter, American educator: b. Sutton, Miss., 19 Oct. 1829. He was graduated from Yale in 1852, studied at the Yale Law School and in 1854 was admitted to the bar. He entered the Union army in 1861, was commissioned colonel in 1864 and in 1866 was mustered out of service. He was a member of the Connecticut legislature in 1868, professor at Cornell in 1868-70 and was founder and first president of Martha's Vineyard Summer Institute. He was president of Mill's College, California, in 1885-86, of the University of North Dakota in 1887-91 and has since been engaged as a lecturer at Drew Theological Seminary, Chautauqua assemblies and elsewhere. He has written 'Fellowship of Slaveholders' (1857); 'High School and Citizenship' (1883); 'Voice and Gesture' (1874-1903); 'History of the Thirteenth Connecticut Infantry' (1867); 'Inaugural Addresses' (Adelphi Academy, 1870), Mills College, 1885); 'The Place of Literature in a College Course' (1887); 'An Educational Party Needed' (1886); 'Free Text-books Necessary in School and College' (1886); 'The Pilgrim Fathers and Civil Government' (1894); 'The Assassination: Who is Responsible' (1901); 'The Nation's Honor Roll: Fiftieth Anniversary of Yale Class of 1852' (1902); 'Shakespeare's Alleged Blunders in Legal Terminology' (1902); 'The Right and the Wrong in our Civil War' (1903); 'Appreciation of Daniel Coit Gilman' (1910); 'Appreciation of George W. Shinn' (1911); 'The Elevation of His Satanic Majesty in Alpha Sigma Phi' (1912); 'Banquet Speech as Grand Senior President' (1913); 'Literal Metrical-Version of the Book of Job,' with 'Essay on The Mystery of Undeserved Suffering in the Light of Evolution' (1914); 'Lights and Shadows in Confederate Prisons' (1915); 'Studies in Shakespeare' (first series); annually for the last five years giving courses of lectures at Cornell on Shakespeare, Milton, The Book of Job, Goldsmith, The Story of Paradise Lost, etc.

SPRAGUE, William, American legislator: b. Cranston, R. I., 12 Sept. 1830; d. 1915. He entered the counting-house of his father, senior partner of the A. and W. Sprague Manufacturing Company, when 16, and afterward with his brother succeeded to the ownership of the business. He was governor of Rhode Island in 1860-63 and was among the most active of the "war governors." He went to the front, participated in the first battle of Bull Run and in the Peninsular campaign and in 1863 was elected to the United States Senate, whereupon he resigned his governorship. He served in the Senate until 1875 and then resumed his manufacturing business. He was married in 1863 to the celebrated Kate Chase, daughter of Salmon P. Chase, from whom he was afterward divorced.

SPRAGUE, William Buell, American Congregationalist clergyman and author: b. Andover, Conn., 16 Oct. 1795; d. Flushing, N. Y., 7 May 1876. He was graduated at Yale University in 1815, studied theology at Princeton University and was ordained in 1819. He held pastorates at Springfield, Mass., in 1819-29, and at Albany, N. Y., in 1829-69. He made an extensive collection of manuscripts, pamphlets and other matter connected with both religious and secular American history, which at his death was divided between the State Library at Albany and Harvard University. He was author of several biographical works besides his most important work, 'Annals of the American Pulpit' (9 vols., 1857-69).

SPRAGUE, Conn., township in New London County, on the Shetucket River, 18 miles north of New London, on the New York, New Haven and Hartford Railroad. It has a Roman Catholic academy and manufactures include hospital supplies, paper and woolen and cotton goods. Pop. 2,551.

SPRAIN, the partial displacement or twisting of a joint with stretching, and more or less injury to the articulating apparatus; the ligaments, tendons and their sheaths being all involved in the injury, while sometimes even small portions of the articulating processes of bones are separated. All joints are liable to this accident, but the wrist and ankle are most frequently the seat of this injury; their liability arising from their immobility, compared with such a joint as the shoulder, which is more liable to dislocation. A sprain is attended with violent pain, and the sufferer feels sick and faint. Swelling and discoloration rapidly take place from extravasation of blood into the sheaths of the tendons and the other surrounding tissues, through laceration of the smaller blood-vessels. Subsequently the swelling is kept up in consequence of the effusion of serum from the incited action which occurs. Thus the joint is much deformed, and great care is required in examining the parts to guard against mistakes and to gain an exact knowledge of the nature of the injury so as to ascertain decidedly and at once whether it be a simple sprain, or whether there be fracture or dislocation. For this purpose the radiograph has been most valuable. If it is a simple sprain the part affected should be laid in an easy position on a pillow and confined in that position by broad slips of bandage crossing the limb and pinned at each end of the sides of the pillow. The part should at first be fomented for an hour or two with cloths wrung out of warm water; afterward it is to be wrapped in cloths wetted with a warm lotion, say of sugar of lead, one dram; opium, one dram; and boiling water, one quart. These cloths, when applied, should be covered with oiled silk or cotton to prevent evaporation. Absolute rest is the principal point to be attended to. To secure this, when there is much restlessness, it sometimes becomes necessary to use splints. In case of inflammation, a purgative may assist. After the pain abates and the swelling disappears, gentle rubbing with a soap and opium liniment is well, and a light flannel bandage should be applied. If the joint remains weak and stiff, stimulating frictions will be found useful, also the pouring of water on the part from a height,

beginning with warm water, and after a time gradually reducing the temperature till the patient can bear it cold. After each application the part should be well rubbed, as otherwise it may become rheumatic; rheumatism is a very common occurrence in parts injured by sprains and fractures. Too great caution cannot be applied in bringing a joint which has been sprained into use, as many diseases of joints are brought on by mismanagement.

SPRECKELS, sprék'elz, Claus, American merchant: b. Darmstadt, Hanover, Germany, 1828; d. San Francisco, Cal., 26 Dec. 1908. He came to the United States in 1846 and settled in Charleston, S. C. In 1856 he went to San Francisco, where he kept a store and later a brewery, and in 1863 established the Bay Sugar Refinery. He imported his raw materials from Hawaii where he acquired large properties, and owned in addition a beet sugar farm of 1,500 acres and a factory at Watsonville, Cal. By financing the Pacific Steamship Company he secured an advantage in ocean freight rates. He invented a new refining process and was by far the most active man of his time in the development of the sugar industry in the western United States.

SPRECKLES, Rudolph, American sugar refiner, capitalist and civic reformer: b. San Francisco, Cal., 1 July 1872. He entered his father's sugar refinery at Philadelphia when a youth, and at the age of 22 became owner of his father's interests in the Hawaiian Commercial and Sugar Company. He was markedly successful in his handling of its affairs and remained in Hawaii until 1898 when he sold out at a figure that netted him a large fortune. He then returned to San Francisco and engaged in banking. He has been prominent in the municipal affairs of San Francisco, lent material assistance at the time of the earthquake and organized and financed the exposure of the city's graft scandals in 1906.

SPREE, sprä, a river of Germany which rises near New Salza in Saxony at a height of about 1,200 feet in the Riesengebirge, and after traversing 227 miles flows by canal into the Havel at Spandau. It has also been connected with the Oder by a canal 17 miles in length. It has been deepened and canalized until it is navigable almost its entire length, and divides into several arms in passing through Berlin. One section of the stream spreads out into a wide marshy region known as the Spreewald.

SPRENGER, sprëng'ër, Jacob, German theologian of the 15th century, who with Heinrich Krämer, was the author of the 'Malleus Maleficarum' or 'Hexenhammer' (1489), which first formulated in detail the doctrine of witchcraft, and formed a textbook of procedure for witch trials. They were appointed inquisitors under the bull 'Summis desiderantes affectibus' of Innocent VIII in 1484, and their work is arranged in three parts—'Things that pertain to Witchcraft'; 'The Effects of Witchcraft'; and 'The Remedies for Witchcraft.' It discusses the question of the nature of demons; the causes why they seduce men, and particularly women; transformations into beasts, as wolves and cats; and the various charms and exorcisms to be employed against witches.

SPRIGTAIL DUCK, or **PINTAIL**, a very distinct species of fresh-water duck (*Dafila acuta*) the male of which is especially distinguished by the great prolongation and narrowness of the middle pair of tail-feathers. Both the females and the young of the latter have the tail-feathers very stiff and acute, but not otherwise peculiar. The sprigtail is a very handsome duck of more trim and slender appearance than most species and, including the tail, may reach two and one-half feet in length. It inhabits the entire northern hemisphere and on the American side breeds in the northern United States and Canada and winters in the Southern States and the West Indies. It is, however, especially an inland duck, and, both when breeding and migrating, associates with teals and mallards in reedy sloughs and about lake margins. Its food being chiefly vegetable, and consisting largely of wild rice, it is one of the best of table ducks. A swift flyer and one of the most alert and wary of ducks, it affords fine sport to the skillful gunner. The nest is always on the ground near the water and hidden in rushes or grass, often at the base of a tree. As with most of the ducks, it is lined with down and the 6 to 12 elongated elliptical eggs are of a plain grayish olive color. See **DUCK**.

SPRING, Gardiner, American Presbyterian clergyman, son of Samuel Spring (q.v.); b. Newburyport, Mass., 24 Feb. 1785; d. New York, 18 Aug. 1873. He was graduated from Yale in 1805 and was admitted to the bar in 1808, but abandoned law for the ministry. He was ordained pastor of the Brick (Presbyterian) Church, New York, in 1810, and continued in that pastorate until his death. He declined the presidencies of Hamilton and Dartmouth Colleges. His publications include 'Essays on the Distinguishing Traits of Christian Character' (1813); 'Obligations of the World to the Bible' (1844); 'The Glory of Christ' (1852); 'Brick Church Memorial' (1861), etc.

SPRING, Leverett Wilson, American educator: b. Grafton, Vt., 5 Jan. 1840. He was graduated from Williams College in 1863, studied theology at Hartford and Andover, and in 1868-81 was engaged in the Congregational ministry. He occupied the chair of English Literature at the Kansas State University in 1881-86 and the same chair at Williams College in 1886-1909 when he became professor emeritus. In 1885 he published *Kansas—the first non-partisan account of the border struggles*—and subsequent historians have generally accepted the conclusions set forth in the book. He has also published somewhat in magazines and elsewhere concerning the Kansas career of John Brown. The principal titles are "Old John Brown at Dutch Henry's Crossing," "Catching Old John Brown," "John Brown and the Destruction of Slavery" and "Colonel Walker's Visit to Old John Brown at Fort Little Sugar Creek." The last two papers were read before the Massachusetts Historical Society. Another contemporary border leader—James Henry Lane—is considered in his "The Career of a Kansas Politician," printed in the *American Historical Review*.

In 1888 he published "Mark Hopkins, Teacher," in 1893 edited the publications con-

cerning the centennial anniversary at Williams and in 1908 the "Induction of President Garfield." He has also written sketches of Williams for 'A History of Berkshire County' (1906) 'A Cyclopaedia of Education' (1913) and other publications.

SPRING, Samuel, American Congregational clergyman: b. Northbridge, Mass., 27 Feb. 1746; d. Newburyport, Mass., 4 March 1819. He was graduated from Princeton in 1771, was licensed to preach in 1774, became a chaplain in the Continental army in 1775, served under Arnold at Quebec and in 1776 left the army. He was ordained in 1777 and from then until his death was pastor of the church at Newburyport. He was instrumental in uniting the two parties in the Congregational Church, was a founder of Andover Theological Seminary, and one of the organizers of the American board of commissioners for foreign missions.

SPRING, the season of the year which follows winter and ushers in summer, and which in the United States includes the months of March, April and May. The first of these months, however, often presents, in the northern States, the harshest features of winter, although at other times genial and springlike. In the hot regions of Central and South America the seasons are divided into dry and wet, and the changes come suddenly and without any transitional periods. The astronomical spring in the southern hemisphere begins 23 September and ends 21 December, corresponding in some degree to the northern autumn.

SPRING, an outflow of water from the earth, or a stream of water at the place of its source. Springs have their origin in the water which falls upon the earth in the form of rain or snow and sinks through porous soils till it arrives at a stratum impervious to water, where it forms subterranean reservoirs at various depths. When the pressure of the water which fills the channels through which it has descended is sufficient to overcome the resistance of the superincumbent mass of earth, the water breaks through the superficial strata and gushes forth in a spring; or it may find some natural channel or crevice by which to issue. In descending and rising through various mineral masses the water of springs often becomes impregnated with gaseous, saline, earthy or metallic admixtures, as carbonic acid gas, sulphuretted hydrogen gas, nitrogen, carbonate of lime, silica, carbonate of iron, etc. When these substances are present in considerable quantity the springs become what are known as mineral springs. Warm and hot springs are common, especially in volcanic countries, where they are sometimes distinguished by violent ebullitions. Some springs run for a time and then stop altogether and after a time run again and again stop; these are called intermittent springs. Others do not cease to flow, but only discharge a much smaller quantity of water for a certain time, and then give out a greater quantity; these are called variable springs. Spring water is generally esteemed as the most desirable for drinking purposes and is bottled and sold in many cities. Consult Fuller, 'Domestic Water Supplies for

the Farm' (1912); Ries and Watson, 'Engineering Geology' (1914). See ARTESIAN WELL; GEYSER; MINERAL WATER.

SPRING, in *mechanics*, an elastic body, structure or contrivance, that yields under force or stress, but returns to its former position or shape when the stress is withdrawn. A strip of soft india-rubber exhibits great elastic qualities, but is not durable enough for use in machinery, and, therefore, springs are made mostly of steel, though many are of iron and brass. Springs are used for various purposes—diminishing concussion, as in carriages; for motive power, acting through the tendency of a metallic coil to unwind itself, as in clocks and watches; or to communicate motion by sudden release from a state of tension, as the spring of a gun-lock, etc.; others are employed to measure weight and other force, as in the spring-balance, as regulators to control the movement of wheel-works, etc.

A spiral spring is one shaped like the main spring or hair spring of a watch. Such a spring lies wholly between two parallel planes whose distance apart is equal to the width of the wire or tape of which the spring is made. They resist distortion, when used, for example, to actuate a watch or chronometer balance, with a force which is very closely proportional to the amount of the distortion. It is this property which insures the isochronism of the motion of a watch or chronometer balance. Helical springs, also commonly called spiral springs, are formed by winding wire into a helix about a right circular cylinder. If wound tight, they resist elongation, or if wound loose, with considerable spaces between the coils, they may be used to resist compression. They are also made in various forms to resist torsional strains. Where a stiff strong spring is desired, flat steel plates, often in groups tied together, are found efficient. These are called laminated springs. The certainty with which a metal spring yields to a given force has led to its employment in the spring-balance, a weighing device consisting essentially of a helical extension spring with a handle above and a hook or support for the thing to be weighed. Frequently a circular pointer is attached which indicates the weight on a dial. Air-cylinders with pistons or plungers are often used as springs, being found especially efficient in cylinder printing presses. Consult Routh, 'Rigid Dynamics'; Thomson and Tait, 'Natural Philosophy'; Kent, 'Mechanical Engineers' Pocket-book' (1916).

SPRING BEAUTY. See CLAYTONIA.

SPRING-BEETLES, or **CLICK-BEETLES**. See ELATER.

SPRING, or **GREEN, FROG**. See FROG.

SPRING-HALT, or **STRING-HALT**, a sudden involuntary twitching or convulsive movement of the muscles of either hind leg in the horse, the leg being raised unnaturally high and lowered with excessive force. Although it may not impair the usefulness of the animal, the defect lessens its value by injuring its gait and, to some extent, its appearance.

SPRING HILL, Nova Scotia, town in Cumberland County, 70 miles northeast of Halifax, on the Cumberland and the Intercolonial railways. There are important coal

mines in the vicinity. Industries include meat packing and the manufacture of furniture and doors. Pop. 5,713.

SPRING HILL, Engagement at. After General Sherman had started from Atlanta, on his march to the sea (q.v.), General Hood, commanding the Confederate Army of Tennessee, marched northward from Florence, Ala., 19 Nov. 1864, to drive General Thomas from Nashville and back to the Ohio River. Thomas, who proposed to concentrate his own army on the line of Duck River and the Nashville and Chattanooga Railroad and to await expected reinforcements, withdrew his advance posts from Pulaski and other points to Columbia, on Duck River, where works were thrown up, covering the approaches from the south. He had there on the 26th about 23,000 infantry and 5,000 cavalry, only 3,500 of the cavalry being mounted. General Schofield was in command. His infantry consisted of two divisions of the 23d corps and the three divisions of Stanley's Fourth corps. Gen. J. H. Wilson commanded the cavalry. General Hood, preceded by General Forrest with 6,000 cavalry, appeared before Columbia on the 26th and with the three corps of Gens. S. D. Lee, A. P. Stewart and B. F. Cheatham, about 40,000 men, and threatened a crossing of the river above and below. During the night of the 27th Schofield withdrew to the north bank of the river, where he remained on the 28th. The two divisions of the 23d corps were placed in position in front of Columbia, holding all the crossings of the river in the vicinity, with Stanley's Fourth corps in reserve on the Franklin pike, ready to move whenever Hood should attempt a crossing above or below the town. Wilson's cavalry held the crossings above those guarded by the infantry. Forrest succeeded in crossing one of his divisions, above Columbia, before noon of the 28th, pushing Wilson's cavalry back on roads leading toward Spring Hill and Franklin, and Hood began crossing his infantry at daylight of the 29th at Huey's Mills, five miles above Columbia, from which a good road leads into the Columbia and Franklin pike, at Spring Hill, 15 miles north of Columbia, a road by which he could intercept Schofield's march to Franklin and strike him in flank. Wilson had dispatched Schofield at 1 A.M. of the 20th that Hood would undoubtedly cross the river at daylight and suggested an immediate withdrawal to Franklin. At daybreak Schofield sent Colonel Post's brigade up the river to ascertain if Hood had really crossed, and ordered General Stanley, with the two divisions of Wagner and Kimball, the trains and the reserve artillery, to Spring Hill, to cover that point and hold the road open for the passage of the entire army. At 8 A.M., Stanley was on the march. On reaching Rutherford's Creek, four miles from Columbia, Kimball's division was halted and faced east to cover the crossing against a possible attack, and remained in this position during the entire day. Stanley, with Wagner's division, pushed on, and it was nearing noon, when his head of column had approached to within two miles of Spring Hill, that he was informed that Buford's division of Forrest's cavalry was approaching from the east. The troops were quickly thrown forward

and Bradley's brigade, deploying as it advanced, drove off Buford's men, just as they had driven back a small force of cavalry and infantry and were about to occupy the village. As the other two brigades came up, they also were deployed from the railroad on the north to the pike on the south, covering the village in a semi-circle, in which was placed the train. Bradley's brigade was sent half a mile to the front and right to occupy a knoll commanding all the approaches from the east. The greater part of the artillery was posted on a rise of ground south of the town. Scarcely had these dispositions been completed when Hood attacked. It was before sunrise when Cheatham's corps began crossing the river, Cleburne's division in advance. Hood accompanied Cleburne on the direct road to Spring Hill. Stewart's corps and Johnson's division of Lee's followed Cheatham, leaving Lee, with the remainder of his corps, in front of Columbia. Cleburne approached Spring Hill about 3 P.M., just as Bradley's brigade was taking position and immediately attacked it, and at the same time an attack was made by Forrest's cavalry at Thompson's Station, three miles north, on a small wagon-train pushing for Franklin, and a cavalry dash on the Spring Hill station northwest of the town. Cleburne's assault on Bradley was twice repulsed, but in a third front and flank attack Bradley was severely wounded and his brigade driven back to the edge of the village, where it was rallied and put in position to cover the wagon-train, part of which had reached Spring Hill. Cleburne endeavored to follow up his advantage, but was repulsed by the fire of eight pieces of artillery. Bradley's loss was about 150 killed and wounded; that of the Confederates was somewhat more. It was now sunset and the engagement ended. The result of it was that the Confederate infantry was checked when within 800 yards of the road, but their cavalry had gained the road both north and south of the town. Stanley, with his one division of not more than 4,000 men, was in a critical position; his nearest support was Kimball, who was more than eight miles in his rear; the other divisions of the army were still at Duck River. But fortunately for Stanley and the whole of Schofield's army, Hood's efforts to press the attack and gain the road miscarried, and Cheatham's corps bivouacked not more than half a mile from the road over which Schofield's army was obliged to pass from Columbia to Franklin. Stewart arrived after dark and formed on Cheatham's right, and by 8 P.M. two corps of Hood's army were in position facing the road and not over half a mile from it. There has been much Confederate contention as to who was responsible for the failure to seize the road and prevent Schofield's escape. Hood says: "Nothing was done. The Federals, with immense wagon-trains, were permitted to march by us the remainder of the night, within gunshot of our lines. I could not succeed in arousing the troops to action, when one good division would have sufficed to do the work."

General Schofield, who had remained during the day at Columbia, started late in the afternoon, with Ruger's division and Whittaker's brigade, for Spring Hill, and when

about three miles from the town, came upon the Confederate cavalry holding the road, which was driven off, after quite a skirmish. Leaving Whittaker to cover a cross-road a mile or two below the town, and to observe the Confederates, who could be seen standing around their camp-fires, Schofield continued his march with Ruger to Spring Hill, which he reached about 7 P.M., and two hours later moved on to force a passage at Thompson's Station. The Confederates withdrew on his approach, the road to Franklin was clear and Ruger took possession of the cross-roads. Schofield returned to Spring Hill, where, meanwhile, General Cox had arrived with his division of the 23d corps. Just before midnight Cox was ordered to start for Franklin, with instructions to take Ruger with him. He was fairly on the road by 1 A.M., of the 30th, at which hour the train of 800 wagons was started to follow Cox. At the very start the train was obliged to cross a bridge in single file, which made the movement so difficult and caused so much delay that Stanley was advised to abandon part of the train, to which he would not consent, and it was almost 5 A.M., before the rear of the train was fairly under way. As the head of the train passed Spring Hill it was attacked by cavalry and some wagons destroyed, but Wood's division, which had followed Cox from Duck River, was thrown on the flank of the train and the enemy driven off. It was near daybreak when the last wagon left Spring Hill. Kimball's division followed Wood's and at 4 A.M. Wagner followed Kimball, his skirmishers remaining until nearly daylight. Opdyck's brigade was rear-guard, and although hard pressed by Confederate cavalry, not a man nor a wagon was left behind. When the rear of the column was leaving Spring Hill, the head of it was at Franklin. Seldom has an army made such a narrow escape from destruction or capture. Consult 'Official Records' (Vol. XLV); the Century Company's 'Battles and Leaders of the Civil War' (Vol. IV, New York 1887-88); Van Horne, 'History of the Army of the Cumberland' (Vol. II, Cincinnati 1875).

E. A. CARMAN.

SPRING HILL COLLEGE, a Roman Catholic institution located at Mobile, Ala. It was founded in 1830 by the Jesuits and remains under their control. It offers, in addition to the collegiate courses, a preparatory course and a commercial course. The degrees of A.B. and B.S. are conferred. There is no endowment; the grounds and buildings in 1915 were valued at over \$500,000; the library contained 15,000 volumes; the students in 1917 numbered 228, and the faculty 35.

SPRING LAKE, N. J., borough in Monmouth County, on the Atlantic Ocean, six miles south of Asbury Park, on the Pennsylvania and the Central of New Jersey railroads. It is patronized as a summer resort, has excellent bathing, good hotels and many fine summer residences. Pop. 1,492; summer pop., 20,000.

SPRING-RICE, Sir Cecil Arthur, British Ambassador: b. England, 27 Feb. 1859; d. Ottawa, Canada, 14 Feb. 1918. He was graduated at Balliol College, Oxford, and after serving as secretary to Earl Granville and as précis

writer to the Earl of Roseberry, he entered the diplomatic service. He was secretary of the legation at Brussels, Washington, Tokio, Berlin and Constantinople, successively; became chargé d'affaires at Teheran, Persia, in 1900; British commissioner of the international debt at Cairo, Egypt, in 1901; and secretary of the embassy at Petrograd in 1903. He was Minister and consul general to Persia in 1906-08; Minister to Sweden in 1908-12; and in 1912 succeeded Lord Bryce (then Sir James) as British Ambassador to the United States. He remained in Washington as Ambassador until 1918, when after his arduous duties during the European War, he was given leave of absence. His health, however, had broken under the strain, and he survived but a brief time. While of a quiet and retiring habit he performed the duties of his office with distinguished ability and unflinching tactfulness through many trying periods. He was knighted in 1916.

SPRING TIDE, the tide which happens at the full moon, which rises higher than common tides. At these times the sun and moon are in a straight line with the earth, and their combined influence in raising the waters of the ocean is the greatest, consequently the tides thus produced are the highest. See **TIDE**.

SPRING VALLEY, Ill., city, Bureau County, on the Illinois River, and on the Chicago, Burlington and Quincy, the Chicago and Northwestern and the Chicago, Rock Island and Pacific railroads, 100 miles southwest of Chicago. It is the centre of a coal-mining region, and mining is the chief industry; it has about 50 manufacturing establishments, including pump factories, foundries, machine shops, etc. There is a national bank and newspapers. It has a public high school and a hospital. Pop. 7,467.

SPRINGAL, an ancient warlike engine, used for shooting large arrows, pieces of iron, etc. It is supposed to have resembled the ballista in its construction, being operated by the release of a wooden spring.

SPRINGBOK, a small South African antelope or gazelle (*Gazella euchores*), about 30 inches in height, and rich cinnamon-yellow on the upper parts, white on the belly, buttocks and face, and with stout, ringed, lyrate horns. It formerly gathered and migrated in enormous herds, but has now become uncommon in the more settled districts. It was remarkable among gazelles for its extreme agility and powers of jumping, and for stripe of long white erectile hairs along the spine. Consult Selater and Thomas, 'The Book of Antelopes' (London 1896), and the writings of South African travelers.

SPRINGER, Alfred, American chemist: b. Cincinnati, Ohio, 12 Feb. 1854. He took his Ph.D. at the University of Heidelberg in 1872, and from 1873 was a member of a firm of manufacturing chemists at Cincinnati. He was co-inventor of the torsion balance, which he patented, and he also patented the aluminum sounding-board for musical instruments. He made many valuable experiments, and has published descriptions of most of them. Author of 'Glycocholic Ether' (1879); 'Pentachloramyl Formate' (1881); 'Reduction of Nitrates by Ferments' (1883); 'A Latent Char-

acteristic of Aluminum' (1891); 'Increase of Segmental Vibrations' (1897), etc.

SPRINGER, Reuben Runyan, American philanthropist: b. Frankfort, Ky., 16 Nov. 1800; d. Cincinnati, 10 Dec. 1884. At the age of 21 he became clerk on an Ohio River steamboat and in 1830 became partner in the grocery firm of Kilgour, Taylor and Company, Cincinnati. In this business and in various investments he accumulated a large fortune which he used for a variety of benevolent enterprises. He contributed over \$200,000 to the building of the Cincinnati Music Hall and gave other large amounts to the Art Museum, the College of Music and the Exposition Building.

SPRINGER, William McKendree, American jurist: b. New Lebanon, Ind., 30 May 1836; d. Washington, D. C., 4 Dec. 1903. He was graduated at the Indiana State University in 1858, and was admitted to the bar in 1861, beginning the practice of law at Springfield, Ill. In 1871 he entered the Illinois legislature and two years later was sent to Congress on the Democratic ticket. During his 10 successive terms he was prominent as temporary speaker, as chairman of the ways and means committee and as a participant in tariff and currency debates. He was the author of the resolution passed by the 44th Congress against the election of any person for a third term in the presidency, and served on the Potter committee which investigated the election of 1876, and also on the joint committee which reported the Electoral Commission bill. As chairman of the committee on territories he was the author of the bill organizing Oklahoma Territory, and of the bill admitting Washington, Montana, North Dakota and South Dakota as States. In 1895 he was appointed judge of the United States Supreme Court for the Northern District of Indian Territory and chief justice of the Court of Appeals of the Territory. In 1899 he removed to Washington and resumed the practice of law.

SPRINGFIELD, Ill., city, county-seat of Sangamon County and capital of the State, is in the centre of the great corn-belt, on the Illinois Central, the Chicago and Alton, the Chicago, Peoria and Saint Louis, the Wabash, the Cincinnati, Hamilton and Dayton and the Baltimore and Ohio railroads, 185 miles south of Chicago; 99 miles north of Saint Louis and near the Sangamon River. It is built on an undulating and well-wooded prairie and is beautifully laid out. The city is compactly built and has well paved and beautifully shaded streets. Springfield is the centre of the great coal mining industry of Sangamon County, whose product of coal in 1918 was 11,694,055 short tons, value \$23,000,000, the largest of any county in the State. This industry in the same year employed 7,453 men and represents a population of fully 35,000. The Illinois State Fair is permanently located here. Large and expensive buildings have been erected at a cost of \$1,650,000. The grounds are extensive and highly improved. The annual fairs have come to be little less than a liberal exposition.

The Capitol Building.—The most conspicuous public building is the State Capitol, which was completed in 1887. It stands in a park of eight acres, and cost over \$4,500,000. The ground plan is in the form of a huge cross and

the superstructure is of the modern classic style. The extreme length is 379 feet and the extreme width 286 feet. The exterior walls are of dressed Joliet limestone, the lofty porticoes of sandstone, supported by columns of polished gray granite. The edifice is three stories high and the massive symmetrical dome, the highest in the United States, is an object of great admiration.

The Lincoln Monument.—Among the historical attractions of Springfield are the Lincoln National Monument and the Lincoln residence. Both are owned by the State and are in charge of custodians. They are open daily to the public. The Lincoln National Monument stands in Oak Ridge cemetery, something over a mile north from the State House. The mausoleum contains the remains of President Lincoln, his wife, two children and one grandchild. The monument and the four heroic bronze groups, three representing the infantry, artillery and cavalry branch of the army, and the fourth, the navy, were designed by the sculptor Larkin G. Meade. It was dedicated 15 Oct. 1874 and cost about \$350,000.

Public Buildings.—Among the prominent structures in Springfield are the United States Courthouse and Post Office, the County Courthouse, the Governor's Mansion, the State Arsenal and Armory, City Hall, Public Library, Reisch Building, Masonic Temple, Franklin Life Building, Ferguson Building, New Leland Hotel, Saint Nicholas Hotel, Sangamo Club, Illini Country Club, Springfield and Saint John's hospitals and David Prince Sanitarium.

Libraries.—In proportion to the size of the city the Springfield Lincoln Library, 185,000 volumes, at one time claimed to be the largest in the United States. It then contained over 58,000 volumes. Here also is the State Library of 70,000 volumes; the State Historical Library of 3,500 volumes, and many rare historical pamphlets, maps, etc., and the Supreme Court Law Library of 18,000 volumes.

Industries.—Springfield is the centre of an extensive coal mining, farming, horse and cattle breeding section and has large manufacturing interests. The invested capital in manufactures amounts to upward of \$7,174,000, with an annual output of products valued at \$11,441,706.14. The Illinois Watch Company has an immense establishment here, employing about 2,000 operatives, also Sangamo Electric Company, manufacturers of electric meters, large implement factory of Montgomery Ward and Company, powder plant of Western Cartridge Company. There are several large printing and publishing houses, textile works, planing and wood working mills, machine shops, woolen mills, breweries, engine, boiler and car works and manufactories of flour, clothing, boots and shoes, saddlery, soap, etc.

Banking and Finance.—On 1 March 1910, Springfield had a net public debt of \$825,800 and the municipal receipts for a single year amount approximately to \$500,000. This item of receipts does not include any school tax. In the same year there were five national banks with an aggregate capital of \$1,450,000, one State bank, \$300,000, and one trust company, \$100,000. The average deposits in all these institutions was \$22,000,000. There are 12 building and loan associations with 6,250 shareholders.

Government.—The city is governed on the commission plan, under revised charter regulations. The municipal expenses for a single fiscal year are approximately \$450,000 exclusive of school expenses, and the municipal receipts for the same period, also exclusive of school tax, amounted to \$500,000. The water-works are owned by the city and have a daily capacity of 12,000,000 gallons. This capacity may be increased almost indefinitely without great cost. There is a complete sewage system of 101 miles, electric light plant, 25 miles of electric street railway, 442 acres of improved park land, value \$515,452, and 85 miles of paved streets.

Education.—The expense of the public schools does not appear in the municipal financial statement, but there is raised annually by taxation a sum sufficient to maintain public schools and to erect new buildings as required. The total estimated value of school property is \$2,243,450. The cost of maintaining the public schools for 1917-18, was approximately \$453,445.38, which does include expenditures for new buildings and permanent improvements. The total enrolment for 1918-19 was 10,066. The total estimated actual value of property, subject to taxation, for school purposes for the year 1917-18 was \$16,299,181 which represents $\frac{1}{2}$ of true valuation. There were employed in the public schools for the year 1917-18 a superintendent, four special supervisors, two school nurses, an attendance officer, 18 principals and 260 teachers.

Religion.—Springfield has a total of 54 churches of all denominations, value \$1,789,000, the Methodist leading with eight, the Baptist next with seven, Roman Catholic six, Presbyterian six, Episcopalian four, etc. There are two Hebrew synagogues and one Christian Science Congregation. Among the charitable institutions are the Home for the Friendless, the Home for Aged Women, the Home for Aged People under the control of the Roman Catholic Church, the Orphanage of the Holy Child and the Colored Old Folks' Home.

History.—Springfield was first settled in 1819 and was laid out in 1823 at which time it became the county-seat. It was first incorporated as a town in 1832 and was chartered as a city in 1840. It was selected as the State capital in 1837 and the State legislature assembled here for the first time in 1839.

Population.—(1890) 24,963; (1900) 34,159; (1910) 51,678; (1919, actual count) 71,969.

WILLIAM H. CONKLING,
Secretary, The Springfield Commercial Association.

SPRINGFIELD, Mass., city; port of delivery and county-seat of Hampden County; on the east bank of the Connecticut River; the terminus of the New York, New Haven and Hartford, terminus of the Connecticut River Division of the Boston and Maine, halfway station of the Boston and Albany Division of the New York Central; 99 miles west of Boston, 134 miles northeast of New York, 314 miles from Montreal—a logical railroad centre. The place is noted for its beauty, being laid out with wide and well-shaded streets and being especially attractive as a residential city. Four bridges span the Connecticut River here. The railroads entering the city built a union depot in 1889 at a cost of \$500,000, which was

replaced in 1919 by a new Union station at a cost of several million dollars, to meet the increased needs of the community. The elevated sections of the city command delightful views of the Connecticut Valley.

Manufactures.—The industries of Springfield represent a capital of \$63,237,707, with an annual output valued at \$75,159,074. The leading manufactures include firearms, motor-cycles, railroad and trolley cars and supplies, candy machinery, envelopes, papeteries, dictionaries, cotton goods, skates, valves, magnetos, buttons, toys and kindergarten supplies, sporting goods, corsets, tobacco products, forgings, machinery, art goods, confectionery, electrical supplies. The United States armory and arsenal are located here. The armory, the chief government arms factory, originally founded in 1794 and in continuous operation ever since, has a capacity of 24,000 rifles per week in addition to repair work, the rate of production varying with the demand. The arsenal was built in 1846 and is modeled after the East India House in London.

Commerce.—The value of imports for the year July 1918 to July 1919 was \$4,000,000; the receipts for the same period, \$52,500. The city has an efficient Chamber of Commerce with a membership of 1,755 and various commercial and social organizations.

Banks and Banking.—Springfield's seven national banks and trust companies with a combined capital of \$3,350,000 have surplus and undivided profits of \$5,900,000 and deposits of \$48,382,492; there are three savings banks with a total of \$50,000,000 in deposits; one safe deposit company with \$500,000 capital; and a bank clearing house which cleared \$153,378,375.24 in a recent year. Springfield's leading financial institution, the Massachusetts Mutual Life Insurance Company, has outstanding insurance of \$490,793,291, and has paid \$143,000,000 to policyholders. The Springfield Fire and Marine Insurance Company has \$1,484,970,034 insurance in force and has paid \$76,223,233.71 in losses since organization.

Public Buildings.—Among the leading buildings in the city are the \$2,000,000 municipal group, consisting of an administration building, auditorium and Campanile Tower; city library, with its science and art museum buildings; the three high school buildings; county courthouse, home buildings of the Springfield Fire and Marine Insurance Company, Massachusetts Mutual Life Insurance Company, Third National Bank, Union Trust Company, Chapin National Bank, Hampden Savings Bank, United Electric Light Company and Springfield Gas Light Company and others.

Education.—The public school system embraces high, grammar, primary, manual training, vocational and kindergarten schools—39 in all, with 680 teachers and 19,000 pupils. The evening trade school is said to be the first of its kind in the United States. The parochial schools enrolled 3,238 pupils in 1915. Springfield is the seat of the American International College, opened in 1885, and the International Young Men's Christian Association College. The city has a public library containing 200,000 volumes, with three branch libraries; and the Hampden County Law Library, dating from 1813. The facilities of the City

Library are perhaps unrivaled in any city of similar size in the country; the library itself is of unusual efficiency. The system of public education is considered one of the most advanced in the United States. The city is the home of three famous publishing enterprises—Webster's Dictionary, the *Springfield Republican* and the *Springfield Union*.

Religion.—There are 65 churches in Springfield, of which 11 are Congregational, eight Methodist, eight Baptist, 14 Roman Catholic, one Unitarian, six Hebrew, three Episcopalian, two Universalist and other denominations.

Parks and Monuments.—There is an extensive public park system comprising 822.07 acres. Forest park has 729.14 acres and contains a collection of birds and animals. There are many small parks and squares throughout the city. In Merrick park stands a statue, "The Puritan," by Saint Gaudens; on Court square and a soldiers' and sailors' monument and a statue of Miles Morgan by Jonathan Scott Hartley; on Pecousic Hill a bust of President William McKinley by Philip Martiny. Hampden Park, containing 54½ acres, has been famous for its horse races and cycling tournaments.

Government.—The city is governed by a mayor elected biennially, and a bicameral council. The municipal appropriation in 1919 was \$4,922,457.28, including \$1,179,132.67 for the school department; \$998,567.97 for the street department; \$352,624.30 for the police department; \$476,153.34 for the fire department. The waterworks are owned and operated by the city; the system cost over \$2,000,000. In 1919 the city had a total debt of \$9,026,500. The assessed valuation of real and personal property in the same year was \$201,786,789.

History.—Springfield was first settled in 1636 by a party of emigrants from Roxbury under the leadership of William Pynchon. Until 1640, when it received the name of Springfield (from Springfield, England, the home of Pynchon), the town was known as Agawam. West Springfield, Chicopee and several of the neighboring towns were then included in its boundaries. On 5 Oct. 1675 during King Philip's War, the town was attacked by Indians and burned. In September 1786 during Shay's Rebellion (q.v.) it was the scene of a riot headed by Daniel Shay. In January 1787 occurred a skirmish between the State militia and 1,000 insurgents led by Shay, in which the latter was defeated. The city was incorporated in 1852.

Population.—Springfield had a population of 2,312 in 1800; (1850) 11,766; (1880) 33,340; (1890) 44,179; (1900) 62,059; (1910) 88,926; (1915) 103,000; (1919) 135,000.

Consult Burt, 'The First Century of the History of Springfield' (1888); Green, 'Springfield, 1686-1886' (1888); Barrows, 'The History of Springfield in Massachusetts' (1911).

CLIFTON D. JACKSON,
General Secretary. Springfield Chamber of Commerce.

SPRINGFIELD, Mo., city, county-seat of Green County, on the Saint Louis and San Francisco and the Kansas City, Fort Smith and Missouri railroads, about 130 miles south of Jefferson City, the capital of the State. In the early part of the Civil War there

occurred in the city and vicinity several battles. One, which is known as the battle of Wilson's Creek, took place 10 Aug. 1861; the Union forces were defeated and the Union general, Nathaniel Lyon, was killed. The city is on the ridge of the Ozark Mountains in a region known for its valuable deposits of zinc and lead. The climate is healthful and warm, temperate about all the year. Its industries are chiefly connected with the mining and marketing of lead and zinc. The chief industrial establishments are two large railroad shops, iron works, machine shops, wagon and carriage factories, furniture factories, flour mills and novelty works. It has an extensive trade in manufactures, lead and zinc and as a jobbing centre for a large part of the southern counties. The principal public buildings are the government buildings, county courthouse, municipal buildings, Saint John's Hospital, Springfield Frisco Hospital, the bank buildings, and several fine building blocks; Landers Building (10 stories), Heer-Andre Building (five stories), Holland Building, Y. M. C. A. Building are all of recent construction. The educational institutions are a State Normal School, Loretto Academy (Roman Catholic), Drury College (Congregationalist), public and parish elementary schools and a public library. There are the National and Confederate cemeteries, parks and in the vicinity many places where the scenery is most beautiful. Pop. (1880) 21,850; (1900) 23,267; (1910) 35,201; (1919 est.) 40,000.

SPRINGFIELD, N. J., township in Union County, on the Rahway River, and on the Delaware and Lackawanna Railroad, eight miles southwest of Newark. The chief manufactures are boot and shoe factories, paper mills and hat factory. Springfield is celebrated as the scene of a battle between the American and British forces, 23 June 1780. The British, under General Knyphausen, advanced from Elizabethtown about 5 o'clock in the morning. They were opposed by General Greene, but owing to the superior number of the enemy he was compelled to evacuate Springfield, which was then burned by the British. During the action the Rev. James Caldwell, chaplain in the New Jersey brigade, is said to have distributed the hymn books from the neighboring Presbyterian church among the soldiers for wadding, saying at the same time, "Now put Watts into them, boys." This battle prevented further advance on the part of the British. The American loss was about 72 and that of the British about 150. Pop. 1,300.

SPRINGFIELD, Ohio, city, county-seat of Clark County, on the Lagonda Creek and the Mad River, and on the Pittsburgh, Cincinnati, Chicago and Saint Louis, the Cleveland, Cincinnati, Chicago and Saint Louis, the Erie and the Detroit, Toledo and Ironton railroads, about 45 miles west of Columbus. Five lines of electric railways provide direct connections with the cities of Columbus, Dayton, Xenia, Urbana, Bellefontaine, Troy and Piqua, Lima.

Manufacturing.—The surroundings of the city were naturally rich in the possibilities of agriculture. An abundance of water power, utilized in woolen, cotton, flour and powder mills, enabled the early settlers to supply many of the needs of a pioneer community. In later

years native genius turned the drift of the city's principal energies into the line of manufactures with the result that the fame of Springfield, as a manufacturing centre, is literally world-wide, and, especially, in respect to the fabrication of implements designed for the planting, cultivation and harvesting of the great staple crops. The developments of more recent years have given these manufactures a varied character, embracing electric motors and fans, leather belting, gas and steam engines, piano plates, machinery in vast variety, tools, mechanical appliances and factory supplies, in iron, steel and brass. Three million copies monthly, periodical publications of high class and national renown, and floral industries exceeded in aggregate extent by no city in the Union, contribute to Springfield's commercial prestige and distinction. Flour, medicine, food, wearing apparel, chemical, coffin, rubber and paper manufactures add variety to the list of Springfield's notable products. A recent industrial survey gives the total number of manufacturing establishments as 285, the amount of capital invested \$30,000,000, the number of wage-earners 9,100, the average annual wages \$5,800,000 and the average value of the annual products \$29,500,000. There were seven large manufacturing establishments of agricultural implements, with an invested capital of \$8,194,543. The 30 foundry and machine shops had a combined capital of \$2,772,036. They had 2,197 employees, to whom was paid annually, on an average, wages amounting to \$1,084,681. The value of the annual products was \$3,097,910. Since 1900 there has been a notable increase in the amount of manufacturing.

Transportation and Commerce.—Ample shipping facilities afforded by the steam lines mentioned, ready access to the coal fields of various States and an excellent supply of natural gas fuel at 30 cents per 1,000 cubic feet are prominent factors in the city's advancement. At an early stage of the development of electric traction lines Springfield took rank as one of the chief centres of Ohio.

Local mercantile interests in lines both of wholesale and retail trade reflect the conditions of a thrifty, growing community.

The Commercial Club, embracing a membership of 700 representative citizens, is the agency for organized effort in the promotion of the growth of the city and the conservation of all its material interests. Four live and progressive daily newspapers give voice and direction to public-spirited sentiment and action.

Buildings and Municipal Improvements.—High School, \$300,000, beautiful building patterned after Congressional Library; Memorial Hall, \$250,000, seats 3,500. The United States post-office building was erected and equipped in 1890 at a cost of \$150,000. The 11 rural free delivery routes add over 6,000 to the number served by the Springfield office. The Clark County courthouse, a handsome structure, is supplemented by a county office building, of striking architectural design and modern construction, the two buildings representing an expenditure of more than \$200,000. The City Building cost \$250,000 and is one of the finest edifices of its kind in the State, providing a city market 300 feet in length and a spacious auditorium in addition to quarters for municipal officers. Fronting the City Building are the

handsome and graceful Kelly fountain and esplanade which cost \$8,000 and were presented to the city by Oliver S. Kelly. The city hospital, founded by the liberal donations of Ross Mitchell and J. H. Thomas and endowed in the sum of \$100,000 in government bonds by John Snyder, was erected and furnished at a cost to the city of \$100,000. It is equipped with every appliance and convenience essential to its use. The city prison and patrol station, the cost of which was \$20,000, is of modern design and construction. Three State fraternal homes have been erected on the hills which border the city, and a fourth, "The Eagles," is under way. These homes are maintained by the brotherhood of the Masonic craft, the Independent Order of Odd Fellows and the Knights of Pythias. The city donated the sites on which the institutions are located, the funds being provided by voluntary contributions amounting to \$100,000. Asa Smith Bushnell gave to the Masonic Home the sum of \$10,000. Thousands of representatives of the fraternal orders annually visit these homes. The Lagonda Club has a handsome building which cost \$25,000. The Young Men's Christian Association building, erected by the gifts of the people of Springfield, cost \$90,000. Asa Smith Bushnell and Edwin S. Kelly each contributed \$5,000.

Snyder Park, a tract of 275 acres, was the gift of John and David L. Snyder. Other donations by the same public benefactors were those of \$25,000 for a memorial bridge and \$200,000 in government bonds in endowment of the park. A memorial arch, erected to the memory of the Messrs. Snyder, by the people of Springfield, at a cost of \$6,000, is to span the entrance to Snyder Park, and was dedicated 4 July 1904. Ferncliff, Springfield's principal burial ground, occupies a site of surpassing beauty. Springfield has an abundant supply of pure water. The waterworks system cost \$800,000. Ample fire pressure is maintained, but the city fire department equipment includes three steam engines of large power.

Churches, Schools, Libraries.—The city has 60 churches, a large number of which are of modern construction and striking artistic beauty. There are 19 public school buildings, four Roman Catholic parish schools, two private business colleges and several private schools. The Springfield Seminary is one of the large city schools. The Wittenberg College, founded in 1845, by the Lutheran Church, has in attendance about 900 students. The Warder public library, which cost \$100,000, is a gift from Benjamin H. Warder. It contains 35,000 volumes and is maintained by an annual appropriation. More than a score of literary clubs contribute to the culture and refinement which are marked characteristics of the people of the city.

Banks and Finances.—There are eight banks—six national and two savings banks. The national banks have a combined capital of \$1,000,000; the six banks have deposits amounting to \$5,214,520. There are two building and loan associations with assets in excess of \$1,500,000. The bank clearings increased from \$27,197,800 in 1910 to \$41,194,503.02 in 1915. The gross receipts of the post office were in 1903, \$163,041, and in 1915, \$443,533.74. The aggregate financial transactions of the post-office, in 1910, were \$1,000,000. The aggregate

value of the real and personal property, as assessed for taxation, for the year 1915 was \$58,712,650.

History.—The plat of the town was made in 1801 by James Demint. The city was chartered in 1850. The life of the city is told by the growth of its industries, charitable institutions, churches and schools. It has been the home of many noted men, among whom may be mentioned Joseph Warren Keifer (q.v.) and Asa Smith Bushnell. Pop. about 63,070.

SPRINGFIELD, S. Dak., city in Bon Homme County, near the Missouri River, 170 miles southeast of Pierre, on the Chicago, Milwaukee and Saint Paul Railroad. The Southern State Normal School is located here. Pop. 675.

SPRINGFIELD, Vt., village and township in Windsor County, on the Black River, 35 miles southeast of Rutland, and on an electric railroad. It has shoddy mills, machine shops and a brass foundry. Pop. town, 4,784; village, 3,250.

SPRINGFIELD (Mo.), Military Operations at. As the central point of southwestern Missouri, Springfield was an important place in military operations during the Civil War. After the engagement at Carthage (q.v.), 5 July 1861, Colonel Sigel retreated to Springfield, where he was joined by Gen. Nathaniel Lyon (q.v.) on the 13th, Lyon assuming command of all the Union forces, and calling for more to make head against the combined forces of Generals Sterling Price and Ben. McCulloch, a call that brought no response. On 1 August, hearing of the Confederate advance, Lyon marched from Springfield with 6,000 men and 18 guns against it, and next day at Dug Springs, 19 miles from the city, his advance encountered and drove back the Confederates under General Rains, with slight loss, and returned to Springfield on the 5th, which he thought he should be compelled to abandon, falling back either to Saint Louis or Kansas, as he was largely outnumbered. He reported the condition of affairs to General Frémont (q.v.) in command at Saint Louis, held his position, and advancing on 10 August, fought the battle of Wilson Creek (q.v.), nine miles southwest of Springfield, and was killed. His army, under Colonel Sigel, retreated through Springfield to Rolla, the Confederates following only to Springfield, which they held until the 25th, when they moved against Lexington. On 13 August, Frémont, hearing of the Wilson's Creek disaster, Lyon's death and the unobstructed retreat of Sigel on Rolla, sent reinforcements to Rolla, and at the end of September he left Saint Louis with an army of 38,000 men and 86 guns to take the field in southwestern Missouri, against Sterling Price (q.v.). His five columns were directed on Springfield. On 23 October, when about 50 miles from Springfield, Frémont sent Major Zagonyi, with about 250 men of his bodyguard and of the "Irish Brigade" (37th Illinois) to advance on the place. Zagonyi reached Springfield on the 25th. It was then held by about 1,000 recruits, some mounted and some on foot, and after several charges Zagonyi routed them, his loss being 15 killed, 27 wounded and 10 missing. Frémont occupied the place on the 27th with 21,000 effective men,

and was about to advance and give battle to the Confederates, when (2 November) he was relieved in command by General Hunter, who withdrew the army to Rolla. Price reoccupied Springfield and began to recruit an army to recover Saint Louis, and had gathered some 8,000 men by 12 Feb. 1862, when he was driven from the place by General Curtis, Price retreating into Arkansas. Springfield now became a depot of supplies, and was well fortified. Early in January 1863 General Marmaduke (q.v.) with 4,000 mounted men and three guns, started from northern Arkansas on a raid into Missouri, and with a part of his command appeared before Springfield on the morning of the 8th. Gen. E. B. Brown, in command of the place, had but short notice of his approach, but gathered some militia from the adjoining country, which, with his regular command, convalescents from the hospitals and some citizens, gave him about 2,100 men. The fight began about 10 A.M. of the 8th and continued until dark. Marmaduke's men drove in parts of the line, captured one gun, carried some of the works and seized part of the town, but Brown held the strongest fort against all efforts to take it. On the morning of the 9th Marmaduke withdrew in the direction of Rolla, after a loss of 20 killed, 105 wounded and 26 missing. The Union loss was 14 killed, 146 wounded and 5 missing.

E. A. CARMAN.

SPRINGFIELD RIFLE. See **ORDNANCE; SMALL ARMS.**

SPRINGS, elastic contrivances of any kind having the power of recovering, by their elasticity, their natural state after being bent or otherwise forced—interposed between two objects in order to impart or check motion or permit them to yield relatively to each other. A common variety of spring is the carriage or automobile spring which diminishes concussion between the body and the frame or wheels. Another variety is the helical spring used to operate valves, etc. Modern carriage (carriages, automobiles, railway cars, etc.) springs consist of finely tempered pieces of steel so formed and fastened together that they strengthen each other, while allowing free play for the natural spring of each plate or leaf to act, and by so doing to absorb a large portion of the vibration and jolting caused by the wheels passing over inequalities in the road. The springs are mounted between the axles and framework, so that the wheels when passing over an obstruction or sinking into a hollow, compress or expand them, in the first instance, the motion being thus partly absorbed and partly passed on to the frame in a much lessened degree, and with the shock considerably deadened by passing through this elastic medium. Carriage and automobile springs are made in a variety of shapes. The elliptic spring consists of two halves fastened together with bolts; the top half is attached to the frame and the bottom half to the axle by bolts or slips in the centre. Varieties of the elliptic are the half-elliptic or semi-elliptic and the three-quarter-elliptic, in which an iron attached to the frame takes the place of one-half or more of the upper part of the ellipse. The grasshopper spring is arc-shaped with linking plates for attaching to shackle. The volute spring is a type now in favor for heavy vehicles.

When a spring made up of several leaves, plates or laminations is compressed, the various leaves must slide upon each other. This sliding motion is constantly taking place while the vehicle is traveling. To facilitate the slide movement the leaves are lubricated. The top member of the ordinary auto or carriage spring is of stout spring steel, with lugs forged on each end of it, by means of which it is attached to the shackles. It is furnished with lubricators and slots through which the oil flows to the various grooves. For high-speed vehicles it has been found advisable to lengthen the spring considerably and increase the circle of which the spring forms an arc. Consequently the spring is more nearly horizontal. In power-driven road vehicles radius rods are used to take up the drive and other thrusts which tend to alter the position of the rear axle in regard to the frame. The rods tend to locate the axle relatively to the frame. Horn plates are used to prevent the side movement of the springs, while in some cases rollers are used to prevent the axle from moving laterally relatively to the frame. The rollers come up against the surface of the horn plates. The helical spring is a length of metal of either round or rectangular section, wound round an imaginary cylinder. It is commonly miscalled a spiral spring. The corkscrew gives an idea of the helical spring. The spiral spring is a length of metal wound in a curve of continually decreasing or increasing radius. When wound it is quite flat. The main-spring and the hair-spring of a watch are spiral springs. The trembler spring is a flat spring used in coils and in contact breakers in order to make and break contact. The volute spring is a combination of the helical and the spiral spring. Helical and volute springs are in general use in modern machinery of several types, but are especially used in internal combustion engines to return the valves to their seatings. Other uses of the helical spring will instantly occur to every reader.

SPRINGS, natural outlets by which ground water reaches the surface. The more common small springs usually result from the outcrop of a nonporous layer below a porous stratum, the water which soaks down through the porous layer being forced to move laterally along the top of the impervious bed until it emerges. This type is usually called the hillside spring. On many steep hillsides or mountain slopes the soil acts as the porous layer, the bed rock as the impervious stratum, and whenever the soil is thin, the water is forced to the surface forming springs or swampy places. Sometimes the water seeps slowly down into the earth along an inclined porous bed, until it reaches a crack or joint, along which it rises rapidly. Such *fissure springs* are often of large size, and frequently have a high temperature, due to the great depth from which the water ascends. A third type of spring, common in limestone regions, results from the emergence of an actual underground river, which flows through a cave dissolved in the limestone. Such springs are frequently of enormous size, sometimes furnishing power to run local mills. Warm or hot springs are commonly termed thermal springs. The temperature varies greatly, ranging from normal to the boiling point. The heat may be due to the proximity of still uncooled volcanic

rocks or to the great depth from which the water ascends along fissures. The hot springs of Yellowstone are probably of the former type, many warm springs of eastern United States appear to be of the latter sort. Practically all ground water carries mineral matter in solution. If this mineral matter is unusual in character or quantity, the spring is termed a mineral spring. Large quantities of lime cause calcareous springs; iron, chalybeate springs; silica, silicious springs; salt, saline or salt springs; hydrogen sulphide, sulphur springs. Many mineral springs are believed to have medicinal value, and much mineral water is bottled and sold. In 1913, mineral water to the value of \$5,631,391 was reported in the United States alone.

SPRINGTAILS, a family of wingless insects of the order *Collembola* distinguished by the possession of an elastic forked caudal appendage, folded under the body when at rest, by the sudden extension of which these insects are enabled to make considerable leaps. The name is popularly extended to any thysanurous insect, as the snow-flea (*Achoreutes nivicola*) and the bristletail (q.v.). Their scales are favorite test-objects for microscopes.

SPRINGVILLE, Utah, city in Utah County, 40 miles southeast of Salt Lake City, on the San Pedro, Los Angeles and Salt Lake and the Rio Grande railroads. The surrounding region is devoted to dairying and to fruit and stock raising, and there are gold, silver, iron and copper mines. Industries include canneries, beet sugar factories and railroad construction shops. Pop. 3,356.

SPRIT, a small boom or pole which crosses the sail of a boat diagonally from the mast to the upper aftmost corner, which it is used to extend and elevate. These sails are accordingly called sprit-sails. A sail attached to a yard hanging under the bow-sprit was also formerly so called.

SPROCKET, one of the projections ("teeth") on a sprocket-wheel which engages the chain, also the name applied generally to any wheel upon which are radial projections that engage the chain passing over it. Perhaps the commonest form of sprocket is found in the bicycle, in which the pedal shaft carries a large sprocket-wheel which drives an endless chain which in turn drives a small sprocket on the axle of the rear wheel. The early automobiles were also largely driven by sprocket and chain mechanism, a practice largely copied from bicycle practice. Sprockets are of various designs, a maximum of efficiency being claimed for each by its originator. Sprockets and chains are also used for power transmission from one shaft to another where slippage is not admissible, sprocket chains being used instead of belts or ropes and sprocket-wheels instead of pulleys. They can be run at high speed and some forms of chain are so constructed as to be noiseless even at high speed.

SPROCKET CHAINS, chains used for power transmission from one shaft to another, of the endless type, and working over sprocket or radical pointed-tooth wheels. They are much used in the bicycle, where the type known as the block-and-side-link is well nigh universal. In this type every other "link" is a block and is

connected to the one following by two steel side plates between which the sprocket tooth moves. This type of sprocket chain was also extensively used in automobile construction but has been displaced by the roller type of chain, consisting of side-links held together by rivets, the latter encircled by a roller. These offer less friction as the chain takes its place on the sprocket. The chief advantage of the sprocket chain as a means of power transmission is its ability to work with very little friction loss without slippage, as is the case with belts and ropes. A fault of the chain is its noise, arising largely from the fact that as the chain stretches and the sprockets wear down in size, the two no longer fit together and the chain begins to rub upon and grind the teeth, thus increasing the working strain. In modern practice the silent gear chain has displaced all other types. Here the chain does not lie with its rivets or blocks between the sprocket-teeth, but carries them rather above, or outside the teeth, and each link is provided with points at one or both ends, which act as teeth to engage the teeth of the sprocket. These points grip the sprocket teeth as they come in contact with it and, having gripped it, they hold the chain in that position, which insures perfect-pitch line effect.

SPROULE, Thomas Simpson, Canadian physician and legislator: b. York County, Ontario, 1843. He was educated at the University of Michigan and at Victoria University, Cobourg, and for a short time practised medicine in Michigan. He later returned to Canada and was a member of the Dominion Parliament in 1878-1911. In 1915 he became a member of the Senate. He was throughout his career a strong supporter of Protestantism and worked earnestly for separate schools for Manitoba.

SPRUCE, or **SPRUCE-FIR**, a coniferous tree of the subfamily *Abietinae* and especially of the genus *Abies*. One of the best known and typical is the Norway spruce (*A. excelsa*), which is indigenous in the north of Europe where it is the loftiest (often 125 feet) of forest trees, but has been transplanted as an ornament to all cool climates. The American spruces are described under **FIR**.

SPRUCE-BEER, a decoction of the young green tops of the black spruce, boiled and evaporated to the consistence of a thick syrup. Spruce beer of good quality may be prepared as follows: Essence of spruce, one half pint; pimento and ginger (bruised), of each five ounces; hops, one-half pound; water, three gallons; boil the whole for 10 minutes, then add of moist sugar 12 pounds (or good treacle 14 pounds); warm water, 11 gallons; mix well, and when lukewarm add a pint of yeast; after the liquid has fermented for about 24 hours it is ready for bottling. The beer is regarded as a diuretic and antiscorbutic, and is relished by many as an agreeable summer beverage.

SPRUCE PARTRIDGE. See **GROUSE**.

SPUR, a metal instrument composed of a shank, neck, and prick or rowel, fastened to the heel of a horseman to goad his horse to greater speed. Its use cannot with certainty be traced further back than Roman times. Rowels first appeared early in the 14th century. The spurs of mediæval knights were gilt and those of esquires silvered. "To win his spurs" meant to

gain knighthood. The Mexicans and Spanish-Americans generally wear large spurs, often of silver, except the rowel, and sometimes beautifully ornamented. The tendency in North America and western Europe is to use spurs much less than formerly.

SPURGE. See *EUPHORBIACEÆ*.

SPURGE-LAUREL. See *DAPHNE*.

SPURGEON, spér'jón, Charles Haddon, English Baptist preacher: b. Kelvedon, Essex, 19 June 1834; d. Mentone, France, 21 Jan. 1892. He was the son of a Congregationalist minister and was educated at Colchester and Maidstone. In 1849 he was appointed usher in a school at Newmarket and soon after engaged in religious work at Cambridge and the neighborhood, being known locally as the "boy preacher." Having joined the Baptist body he accepted the pastorate of a small Baptist congregation at Waterbeach at 18. Becoming known for his eloquence he was called, in 1854, to the pastorate of the Baptist chapel in New Park street, Southwark, and this, becoming too small for his audience, his congregation successively removed to Exeter Hall and the Surrey Music Hall, and ultimately built, in 1861, the great Metropolitan Tabernacle, which could accommodate 6,000 persons. Here he preached and labored for the rest of his life, his discourses attracting hearers from all parts of the world. Besides his ordinary ministrations and the publication from 1855 of a weekly sermon he founded the Pastors' College, at which the ministers of 36 London chapels were trained by him, the Stockwell Orphanage, almshouses, schools, etc. Earnestness, simplicity, directness, liveliness and not infrequently a genuine touch of humor were the chief characteristics of his sermons. Sagacity, common sense, straightforwardness, hatred for sham and falsity were prominent traits of his character as a man. He was the author of numerous volumes, among which the best-known are 'The Saint and his Saviour' (1867); 'John Ploughman's Talk' (1868); 'Feathers for Arrows' (1870); 'The Treasury of David,' a commentary on the Psalms—extending to seven volumes (1865-80); 'Types and Emblems' (1875); 'The Metropolitan Tabernacle and its Work' (1876); 'Farm Sermons' (1882); 'The Present Truth' (1883); 'Storm Signals' (1886); 'Salt Cellars' (1889); and he edited the monthly magazine *Sword and Trowel*. Consult 'Life' by Shindler (1892) and 'Autobiography Compiled by his Wife' (1900).

SPURGEON, Thomas, English Baptist clergyman, son of C. H. Spurgeon (q.v.): b. London, England, 20 Sept. 1856; d. 20 Oct. 1917. He was educated at the Pastors' College, studied art and visited Australia and Tasmania in 1877 and in 1879. In 1880-89 he was in charge of the Baptist Church at Auckland, New Zealand, and was evangelist of the New Zealand Baptist Union in 1889-93. From 1894-1917 he was pastor of the Baptist Church, Metropolitan Tabernacle, London. He was editor of *Sword and Trowel* and was publisher of 'The Gospel of the Grace of God' sermons (1884); 'Scarlet Threads and Bits of Blue,' poems (1892); 'My Gospel,' sermons (1902), etc.

SPURRY, a plant of the genus *Spergula*, order *Caryophyllaceæ*; annual herbs, with the

narrow or awl-shaped stipulate leaves fascicled at the swollen nodes of the succulent stems, and thus appear as if in whorls. The flowers are small and white in terminal, loose cymes, and have their parts in fives. *S. arvensis* is the common corn-spurry or yarr, a weakly spreading slender plant, generally glabrous, and with numerous flowers. It has been naturalized from Europe, where it is found in sandy fields, and is sometimes cultivated for green manure and for a rapidly growing fodder, or soiling crop, well liked by cattle and poultry. The sand-spurries are delicate plants of the closely allied genus *Tissa*. Found in salt-marshes and sea-beaches, with small pink flowers.

SPURZHEIM, spoorts'him, Johann Friedrich Kaspar, German phrenologist: b. Longwich, near Treves, Rhenish Prussia, 31 Dec. 1776; d. Boston, Mass., 10 Nov. 1832. He was educated at Vienna, where he became acquainted with Franz Joseph Gall (q.v.), the founder of the system of phrenology. To this study Spurzheim became exceedingly partial; and he soon joined Gall in making inquiries into the anatomy of the brain. They quitted Vienna in 1805 to travel and went in 1807 to Paris. From that period Spurzheim traveled and lectured in England, Scotland and Ireland. In 1832 he visited the United States and began his lectures in Boston, but death soon interrupted his labors. He published 'The Physiological System of Drs. Gall and Spurzheim' (1815); 'Sur la Folie' (1818); 'Essai philosophique sur la Nature morale et intellectuelle de l'Homme' (1820); 'A View of the Elementary Principles of Education' (1821), etc. Consult Carmichael, 'Memoir of the Life and Philosophy of Spurzheim' (1833). See also *PHRENOLOGY*.

SPUYTEN DUYVIL (spi'tn di-vil) **CREEK**, a tidal channel connecting the Hudson River with the Harlem and forming the northern boundary of Manhattan Island, New York. Its name is derived from the Dutch "*Spyt den duivel*" (in spite of the devil), and is supposed to have been derived from the following circumstance: When the English fleet appeared in New Amsterdam (New York) Harbor, the governor's trumpeter was sent to warn the farmers up the Hudson and summon them to the defense of the city; on reaching this creek he found no ferryman willing to take him across on account of the high wind, and swore to cross the stream "*spyt den duivel*"; but was drowned in the attempt to swim across. The creek is crossed by a railway drawbridge near the Hudson.

SPY, in *military usage*, a secret emissary sent into the enemy's territory or encampment to inspect their works, ascertain their strength or movements and report thereon to the proper officer. As the service is most dangerous, for it is the custom when a spy is caught to put him to an ignominious death, a general has no right to compel any person, whether a subject of his own or the enemy's country, to undertake it. The proper business of a spy is to obtain intelligence and he must not be employed to take the lives of any of the enemy. An officer or soldier found within the enemy's lines should not be treated as a spy if he is clothed in his own uniform, but is dealt with either as a deserter or prisoner of war; but if

wearing his enemy's uniform or civil dress he is liable to be hanged. The American Civil War offered many instances of great daring on the part of spies, Union and Confederate, and in numerous cases their exploits resulted in tragic deaths. While spies are undoubtedly induced to perform their perilous work, in numerous cases, by hope of reward, yet there have also been many examples among them of pure and devoted patriotism. In the Russo-Japanese war several Japanese officers of rank and family position, who sought, in the disguise of coolies, to blow up a railway bridge in Manchuria, were promptly hanged as spies, and the spy record of the World War would fill many volumes.

SPY, The. 'The Spy; a Tale of the Neutral Ground,' Fenimore Cooper's second novel, published in 1821, was the earliest American novel to win wide and permanent fame and may be said to have begun the type of romance which dominated native fiction for 30 years. The share of historical fact in the story, indeed, is not large, but the action takes place so near to great events that the characters are all invested with something of the dusky light of heroes, while Washington moves among them like an unsuspected god. The book is full of swelling rhetoric and the ardent national piety of Cooper's generation. Fortunately Cooper saw the advantage of making his British out to be enemies worth fighting, if only in the interest of the plot, which ranges back and forth over the neutral ground between the two armies with great haste and sweep. To rapid movement Cooper adds the merit of a very real setting. He knew Westchester County, where he was then living, and its sparse legends as Scott knew the border. The topography of 'The Spy' is drawn with a firm hand. With his characters, Cooper is not uniformly successful. Accepting for women the romantic ideals of the day, he cast his heroines in the conventional mold of helplessness and decorum. The less sheltered Betty Flanagan, no heroine at all in the elegant sense, is amusing and truthful. Of his men, too, the gentlemen are little more than mere heroes, whatever the plain fellows may be. But Harvey Birch, peddler and patriot, his character remotely founded upon that of a real spy who had helped John Jay during the Revolution, is essentially memorable and arresting. Gaunt, weather-beaten, canny, mysterious, he prowls about on his subtle errands, pursued by friend and foe, sustained only by the confidence of Washington, serving a half supernatural spirit of patriotism which drives him to his destiny, at once wrecking and honoring him. This romantic fate also condemns him to be sad and lonely, a dedicated soul. No character in American historical fiction has been able to obscure this first great figure. H. L. Barnum's 'The Spy Unmasked; or Memoirs of Enoch Crosby, alias Harvey Birch' (1828; 5th ed., 1864) claimed to identify the original.

CARL VAN DOREN.

SQUAD, in the army, a small body of troops assembled for drill, inspection or other purposes. A troop of cavalry or a company of infantry is usually divided into as many squads as there are sergeants or drill-instructors to train them. The awkward squad is composed of those recruits who have not received sufficient training to take part in regimental drill.

SQUADRON, (1) the principal division of a cavalry regiment in some European armies, commanded by a captain, and usually of 100 to 150 horsemen. This body is subdivided into two troops. Three to six squadrons form a regiment. When in line one yard in the length of the front is allotted for each man and horse; the space in line between every two squadrons is equal to one-quarter of the extent occupied by each squadron. (2) *In the navy* a squadron is a number of vessels employed on any particular service or station, smaller than a fleet, under the command of a commodore or junior flag-officer. A United States navy squadron may consist of 11 or less battleships. When a large fleet is assembled, they are usually divided into the van, centre and rear squadrons.

SQUARCIONE, **Francesco**, frân-chês'-kô skwâr-chê-ô-nê, Italian painter: b. Padua, 1394; d. there, 1474. In early life he traveled in Greece and Italy, where he became acquainted with the masterpieces of ancient sculpture. He formed a collection of busts, torsos and bas-reliefs (probably casts) and founded the Padovan school of painting, which produced Mantegna and Zoppo. One of his latest works is 'A Madonna and Child,' now in the possession of the Lazzard family at Padua.

SQUARE, (1) *in geometry*, a quadrilateral figure, both equilateral and equiangular, or, in other words, a figure with four equal sides and equal angles. In measuring superficial areas it is only necessary to multiply one side by itself to have the area of the square, because each of the sides may be considered as the basis or as the perpendicular height. Thus a square the sides of which measure four feet is equal to 16 square feet, that is, 16 squares each one foot high and one foot broad. To square a figure (for example, a polygon) is to reduce the surface to a square of equivalent area by mathematical means. It has often been attempted to square the circle, but this can be done only approximately. (2) *In arithmetic and algebra* the square of a number is the number or quantity produced by multiplying a number or quantity by itself. Thus 64 is the square of 8, for $8 \times 8 = 64$. (3) *In military tactics*, a body of infantry formed into a rectangular figure with several ranks or rows of men facing on each side, with officers, horses, colors, etc., in the centre. The front rank kneels, the second and third stoop and the remaining ranks (generally two) stand. This formation is usually employed to resist a cavalry charge. Hollow squares are frequently formed with the faces fronting inward when orders and instructions, etc., are to be read and the like. (4) Any of a great variety of objects more or less rectangular, as a city block, a pane of glass, a simple measuring instrument for determining right angles, usually made in the form of an L or T. A geometric square, however, may be quite a complicated instrument.

SQUARE ROOT. **Arithmetical.**—The square root of a number is one of its two equal factors. It is indicated by the fractional exponent ($\frac{1}{2}$) placed at the right, and above the number, thus $16^{\frac{1}{2}}$, or by the radical sign ($\sqrt{\quad}$). The two equal factors of 16 are 4 and 4, either one of which may be taken as its square root. The square roots of many

numbers are approximate only and are represented by a whole number and a decimal, the latter carried out as many places as the approximation is desired, as example, $\sqrt{19} = 4.358899+$. The square root of fractions may be found by extracting the root of the numerator and denominator, but a more practical method is to extract the root of the resulting decimal. Illustration of the method employed in finding the square root of 576:

$$\begin{array}{r} 576(20 \\ 20 = 400 \quad 4 \\ \hline 2 \times 20 = 40 \quad 176 \quad 24 \\ (40 + 4) \times 4 = 176 \end{array}$$

Since the number 576 has three figures its square root will be composed of tens, and units. The number of tens in the root will be 2, and the square of 2 tens, or 20, will be 400. (See

FIG. 1.

FIG. 2.

Fig. 1). But inasmuch as there is still a remainder of 176, such additions must be made to the square as will take up this remainder, and still keep the figure a perfect square. The necessary additions are the two rectangles B and C and the small square D (see Fig. 2). The remainder 176 divided by the length of the rectangles, 2×20 , will give the width of the additions, which is 4, and this width is also the side of the small square D; therefore the total length of the additions will be $40 + 4$, and the area of the additions 4 times this length, or 176, which completes the square whose area is 576, and whose square root is 24.

Algebraic.—The preceding rules, with the exception of those relating to decimals, are applicable to algebraic quantities. The square root of an algebraic quantity, however, may be positive or negative.

The square root of a negative quantity is imaginary, and is usually factored into two quantities, one of which is real, and the other expressed by $\sqrt{-1}$. Thus the square root $\sqrt{-ab} = \sqrt{ab} \sqrt{-1}$.

The square root of algebraic quantities affected by other roots is indicated by multiplying its exponent, or index by 2, wherever possible the square root is first extracted, and the multiplication avoided.

The indicated square root of an imperfect square, in algebra, is called a quadratic surd. To extract the square root of a binomial surd, such as $\sqrt{a + \sqrt{b}}$, there are many methods; one is to reduce the surd term so that its coefficient shall be 2. Then separate the rational term into two parts whose product shall be the

quantity under the radical sign. Extract the square roots of these parts, and connect them by the sign of the surd term.

Square root finds its application in all branches of mathematics, and in the natural sciences. Its use is fundamental.

SQUARING THE CIRCLE. See QUADRATURE OF THE CIRCLE.

SQUASH, a garden vegetable, the fruit of several species of the genus *Cucurbita* (order *Cucurbitaceae*). They are vine-like tendril-bearing herbs, with large rough leaves on long hollow stalks, have large monocious yellow flowers borne singly in the axils of the leaves, and followed by hard fruits of many forms and sizes. They are natives of warm climates, but are cultivated as annuals in temperate regions throughout the world. The summer squashes are derived from *C. pepo* mainly, and the winter kinds principally from *C. maxima*, though *C. moschata* also enters into many varieties. The first species, which is also parent of the pumpkin (q.v.), has given rise to the scallop, pattypan and summer crookneck squashes, the first known in southern markets as simlins, symblings and various similar names; the third is the parent of the winter and Canada crookneck, China and cushaw squashes. *C. moschata* and *C. pepo* have been crossed artificially, but none of these species are known to cross under field conditions, and the other pairs among these three species have not been crossed artificially.

Squashes thrive best in long seasons, in warm situations and upon light, loamy but only moderately rich well-drained soils. In the North they are often planted too early and are injured by late spring frosts and they often fail to mature all their fruits because the early frosts of autumn injure the vines. To obviate these results the plants are frequently started under glass upon pieces of sod or in pots and are transplanted to the field when seeds could be safely planted. About three weeks is the maximum time to allow between sowing and transplanting, the plants being likely to be too large for best results if older. The soil should be deeply and finely prepared and marked off in checks prior to sowing. For "bush" and summer squashes 4×4 feet is the usual distance; for winter and viny kinds 8 or 12 feet. Most growers allow only two or three plants to each "hill," but plant 12 or even more seeds in the hills to guard against contingencies. The ground is kept cleanly cultivated until the vines prevent tillage. In the North, the vines should not be allowed to root at the joints because this prolongs the vegetative period, and here if one fruit sets long in advance of others upon a vine it is usually cut off since other fruits often fail to form. Two or three squashes are usually calculated upon per vine for winter varieties; summer kinds will often continue to bear until frost if the fruits are removed as soon as they attain edible size. Winter squashes may be successfully stored for several months but they should be gathered before frost, handled with extreme gentleness to avoid the slightest bruise even to the hardest specimens and kept at a rather low temperature in a dry atmosphere until needed for use.

Several insects feed upon the squash and sometimes prove troublesome when very abundant. Probably the best known of these is the

squash bug (*Anasa tristis*) which appears from its hibernating quarters about the time the earliest plants appear. The eggs are laid upon the foliage and in about a week the scarlet larvæ emerge. They pierce the tissues with their stout beaks and suck the juices and as they grow they turn gray, becoming dark brownish gray when mature. The adults are about an inch long and there is a seemingly constant succession of overlapping broods from midsummer onward, insects in all stages of development being found. There are, however, in the North usually only two broods. The plan found most satisfactory in controlling these insects is destruction of the vines and immature fruits as soon as the crop can be gathered in the autumn. The squash vine borer, the squash lady-bird beetle, the cucumber beetle and several other insects also feed upon the squash. See CUCUMBER; MELON, etc.

SQUATTER, a person who settles on public or new lands without any title. In Australia the sheep-farmers, who occupy the unsettled tracts of land as sheep-runs under lease from government at a nominal rent, are also called squatters.

SQUATTER SOVEREIGNTY, a term designating the right of occupation acquired through undisturbed possession of public lands for a certain number of years by settlers originally unauthorized. Public lands or public domain belonging either to the nation or individual States, from the necessities of government and the usual operations of capitalists, became an object of speculation, and were accordingly sold from time to time in large tracts to capitalists and speculators, who generally resided at a great distance from the lands thus purchased by them. Their lands being thus entirely out of their view and control were of course continually intruded upon and possession taken here and there by emigrants from the more populous towns, who put them under cultivation and erected houses and buildings upon them for the common purposes of agriculture. These settlers came to be familiarly known as squatters, a name naturally derived from the act of settling upon lands in the manner practised. By the lapse of time the mere possession of these settlers, without any formal title to the land, ripened into what they considered to be a right, although the titled proprietors of the soil were frequently wholly ignorant of such occupation of their property. Often, after a long series of years, it became impossible to dispossess them, whatever their possession, in its origin, may have been. It is true that the proprietors might, and did institute legal processes and recovered judgment against the occupants, but the officers of justice frequently could not execute the sentence of the law and dislodge them from their possessions. Instances not unfrequently occurred where the officers of justice and the proprietors themselves, or their agents, were shot at or suffered other acts of violence from the occupants. In this critical exigency, which threatened the public welfare, and which was perhaps exaggerated by those men who wished to avail themselves of the occasion to obtain popularity for political purposes, it was thought necessary to pass laws which were to a great extent similar to the Roman agrarian laws and which deprived the

technical proprietor of a portion of his rights and transferred them to the possessor who had occupied and improved the land.

Under colonial laws and usages a title to land by mere occupancy could not be acquired by a possession short of 60 years. By one of the first laws promulgated by a State of the republic on the question, the legislature of Massachusetts in 1808 shortened this term to 40 years.

This essential change in the legal rights of the titled proprietors, in violation of what they deemed to be the fair intent and meaning of their contracts, caused much excitement and dissatisfaction among them. Generally, it may be said that there evidently was hardship on both sides; it was not equitable, on the one hand, that the proprietor should be deprived of his land, nor on the other that an innocent occupant who had been suffered to remain in possession for 30 or 40 years, undisturbed by the proprietor, should be suddenly expelled and stripped of the fruits of the labor of a whole life. By way of alleviating the difficulties of the case, it was provided in this law of 1808, agreeable to a well-known principle of the Roman code, that when the proprietor should institute a process to recover his land the occupant should have a right to claim an allowance for the value of the improvements which he had made upon the lands thus occupied by him, and which were called in the Roman law *meliorantes* or *melioramenta*, and by analogy in the popular language of New England, *betterments*, *improvements*, which might have been taken to convey the idea of *melioramenta* being already used in New England in the sense of occupation.

In practice, the law was more unequal in its operation as regarding the proprietor of the land, from another circumstance; for he being usually a non-resident or stranger, and the occupant being an inhabitant of the same territory from which the jury was taken who were to try the question of right between the parties, the proprietor was in the more danger of suffering from the prejudice or hostility of the jury.

The law remained in operation, and the lapse of time rendered it less and less unequal and injurious in its effects; finally it became the model of similar laws for all other States of the Union which respectively claimed the right to legislate upon the matter according to local needs.

And from this claim for legislation according to local needs arose the cry of "popular sovereignty" which became identified with "squatter sovereignty" in that its adherents, especially from 1847 to 1861, advanced and strenuously advocated the theory that the question of slavery in a State or Territory should be decided by the electorate of the State or Territory and not by Congress. See also PUBLIC LANDS, BOUNTIES.

SQUAW-BERRY, or **SQUAW-HUCKLEBERRY**, the deerberry, genus *Vaccinium stamineum*, a bush native to the eastern part of the United States. The bush rarely grows to any height and the berry is very unsavory. The bush, however, has pretty racemed flowers with white recurved corolla and yellow stamens.

SQUAWFISH, a fish of the genus *Ptyochelus oregonensis*, inhabiting the fresh water bodies in California, and commonly known there

as the "Sacramento pike." It grows sometimes to be five feet in length and is one of the largest species of the carp family to be found in American waters.

SQUAWROOT, skwá'röt, a fleshy plant, *Conopholis americana*, of the family *Orobanchaceæ*, native of the eastern part of the United States. It is generally root-parasitic and found among fallen leaves in oak woods. It is leafless, grows to a height of three to six inches and as large around as a man's thumb. Fleshy scales entirely cover the plant and the flowers are in axils of these scales. The blue cohosh, *Caulophyllum thalictroides*, is in rare instances also called squawroot.

SQUAXON. See SALISHAN INDIANS.

SQUETEAGUE, skwě-täg'. See WEAK-FISH.

SQUID, any 10-armed cuttlefish (q.v.; also CEPHALOPODA), not a sepia or spirula (q.v.). The squids are divisible into several groups and range in size from less than an inch (*Idiosepien*) to 75 feet or more in length, when the arms are outstretched. They are found in all oceans, and most of the genera are nearly cosmopolitan. The small families *Sepiidae* and *Idiosepiidae* are confined to the Pacific, and the *Chroteuthidae* to the Atlantic, but the others are practically world-wide in their distribution and pelagic as well as littoral in range. Together these families form the dibranchiate suborder *Decapoda*. Most of the squids belong to the shore-haunting *Loliginidae* or else to the pelagic family *Ommastrephidae*. In both, the gladius "pen," or "cuttlebone," is long and chitinous instead of broad and calcareous as in the sepia proper. The old European names "calamary" or "pen-and-ink fish" refer to the pen-shape of this internal support, which is nearly or quite as long as the back, and to the reservoir of inky dye which they discharge when alarmed. In the *Loliginidae* it is flat, pointed in front and has the shaft keeled on the ventral side; in the *Ommastrephidae*, it is horny, narrow and terminates in a hollow cone at the posterior end. There are many species, both existing and fossil.

The common squid of the north Atlantic coast of the United States is *Loligo pealii*, which after several years of slow growth become 12 to 18 inches long. The color when living is very changeable, owing to the alternate contraction and expansion of the color-vesicles (chromatophores, q.v.), but red and brown tints prevail, and the general effect is great beauty. These squids lay their eggs in midsummer in large bunches of long gelatinous capsules on shelly and weedy bottoms and along rocky coasts. This species is often found in great numbers in summer close to the shore of Maine and northward and many of them are stranded on the beaches. All the squids are caught by sea fishermen to use as bait.

The "flying squids" of the genus *Ommastrephes* are so named from their habit of leaping from the sea, sometimes to such a height as to land them upon the decks of vessels. They are met with chiefly far from land; but one small species (*O. illecebrosa*) is frequently seen in large companies near the New England coast. Verrill describes its attack upon schools of small fishes in which it resembles squids generally. All the species are fish-eaters and are

themselves the prey of larger fishes and of porpoises and the various whales, turtles, etc., of the sea. "In attacking the mackerel," says Verrill, "they would suddenly dart backward among the fish with the velocity of an arrow and as suddenly turn obliquely to the right or left and seize a fish, which was almost immediately killed by a bite in the back of the neck with the sharp beaks . . . cutting out a triangular piece of flesh." They are mainly nocturnal in activity.

To this family belong the "giant squids" of the genus *Architeuthis*, which occur in Arctic and sub-Arctic seas, and are occasionally stranded on the shores of Norway and Greenland, or found in part in the stomachs of captured sperm whales, for which they form an important food-resource. These giants, which probably reach a great age and frequently exceed 50 feet in length, including the arms, have such strength that they would drag down a large boat, if given an opportunity, and cases are known where men in the water, seized by even small specimens, have escaped with great difficulty. Preserved remains and papier-mâché models may be seen in many museums.

Consult Cook, 'Mollusca' (London 1895); Kingsley, 'Standard Natural History' (Vol. I, Boston 1885); Verrill, 'Invertebrates of Vineyard Sound' (Washington 1874).

SQUIER, skwir, Ephraim George, American archaeologist: b. Bethlehem, N. Y., 17 June 1821; d. Brooklyn, N. Y., 17 April 1888. He engaged for a time in teaching, was connected with the village newspaper and studied engineering. He was employed on the *New York State Mechanic* in 1841, and in 1843 went to Chillicothe, Ohio, where he was on the staff of the *Scioto Gazette* and also clerk of the legislature. Soon after removing to Ohio he began a series of investigations concerning the ancient mounds in Ohio and the neighboring States. In 1849 he was chargé d'affaires to the Central American States, was secretary of the Honduras Inter-oceanic Railway Company there in 1853, in 1863-65 he was United States commissioner to Peru, and appointed consul-general to Honduras in 1868. While performing the duties of these various offices he prosecuted an extensive series of researches and became generally recognized as the principal authority on American Indian archaeology. He was afterward chief editor of Frank Leslie's publications, and in 1871 was active in organizing the American Anthropological Society, of which he was the first president. A severe illness in 1874 incapacitated him for further research, though he recovered sufficiently to complete the revision of his work on Peru. His publications include 'Ancient Monuments of the Mississippi Valley' (1848); 'Aboriginal Monuments of the State of New York' (1851); 'Serpent Symbols' (1852); 'States of Central Peru' (1861); 'Peru: Incidents and Explorations' (1877), etc.

SQUILL. See SCILLA.

SQUILLA. See CRUSTACEA; MANTIS-SHRIMP.

SQUINT, in architecture, an oblique opening passing through the walls of many old churches, usually constructed for the purpose of enabling a person in the transepts or aisles to see the elevation of the Host at the high

altar. Generally they are not above a yard high and two feet wide, but sometimes they form narrow arches 10 or 12 feet in height.

SQUINTING. See VISION, DEFECTS OF.

SQUIRE. See ESQUIRE.

SQUIRREL, a typical member of the rodent family *Sciuridae*. The squirrels form the sub-family *Sciurinae*, the members of which are of slender form and have long bushy tails. All squirrels have well-developed clavicles and the two bones of the lower leg well-developed and distinct; the premolar teeth are two above and one below, but the first upper one is small and usually deciduous; the molars, three in each jaw, broad, tuberculate and rooted; the incisor teeth are compressed and the palate broad. About 15 genera with very numerous species and sub-species are distributed throughout the world except in Australia. The typical species are diurnal and strictly arboreal, but some of the ground-dwelling species are transitional to the terrestrial and burrowing marmots (subfamily *Arctomyinae*), and some are nocturnal. They are chiefly vegetarian, but differ much in the exact nature of their food; most of them partake more or less of an animal diet and many habitually rob the nests of birds of both eggs and young. In cold and temperate climates most species hibernate more or less completely and gather stores of nuts, grains and other foods for the winter months. Some species are known to migrate occasionally in large numbers. The species are of small or moderate size, the largest equaling a cat and the smallest a mouse. Squirrels are adaptable creatures and live under a great variety of climates and conditions, the two principal centres of development being regions physically so different as the Malayan Islands and North America, in the latter of which five genera and 120 species occur. The typical genus *Sciurus* includes species mostly of proportionally large size with magnificent bushy tails, no cheek-pouches, the thumb rudimentary and without nail, and the first upper premolar absent or minute. Of the 75 species, approximately, of this genus, fully one-half are Oriental.

Few native American mammals are better known or more beloved than the gray squirrel (*S. carolinensis*), sometimes called the cat squirrel, and, in its melanistic phase, the black squirrel. It abounds in hardwood forests from Canada to Florida and westward to Minnesota, and in the lowlands as well as the mountainous districts. As might be expected from this wide range, it splits into a number of distinct races. This species reaches a length of about 20 inches, of which the tail is nearly one-half and more rounded and bushy than in any other species. The eye is large, full and bright, the ears erect and pointed, but not tufted, and the color rusty gray above, more or less brown along the back and paler below. In the parks and more open parts of even large cities, wherever suitable trees supply a home and a refuge from cats and dogs, the gray squirrel has become semi-domesticated.

Its active arboreal habits and sprightly appearance have done much to make the squirrel the admitted type of frolicsomeness and sport. The food consists of nuts, acorns, seeds, fruits,

etc., and these animals evince economic and frugal habits, in that they accumulate during the autumn a store of provisions, which is deposited in the nooks and crannies of trees. The nest and dwelling-place consists of a spherical structure formed of intertwined twigs with attached leaves lined with leaves and bark and is generally placed in the fork of a bough, in an inaccessible situation in the top of a tall tree. Cavities in trees are similarly lined and serve as nurseries and shelters in which to hibernate. The squirrels exhibit a great attachment for their respective nests, one pair generally occupying the same tree and nest for a long period. From three to four young are produced at a birth, usually in June, the young remaining in the parent nest until the following spring. When engaged in eating, these animals grasp the nut or other food in their fore-paws, sitting meanwhile on their haunches and gnawing off, by aid of their powerful teeth, the hard outer coverings, and even peeling the kernel before eating it. The bushy tail of the squirrel, besides serving, when folded round the body, to retain the heat, assists through its outspread hairs in supporting the animal in its aerial leaps, a function subserved in other squirrels by special developments of the skin.

Before the deforestation of this country had destroyed so many of its natural haunts this species was extremely abundant and not only sometimes raided cultivated fields to the great loss of the farmer, but occasionally migrated in great numbers, even crossing large rivers like the Ohio. Squirrel shooting is a favorite pastime with many, and were it not for the destruction which it entails of such lovable and sprightly animals could be commended as one of the pleasantest of sports, the pursuit of which takes one into forests of noble old trees in the most exhilarating season of the year. It necessitates long cross-country walks without the assistance of a dog, and requires a quick eye and steady hand to bring down the alternately appearing and disappearing game as it leaps and bounds among the topmost branches or projects itself through space from tree to tree. The practice of the Kentucky pioneers of "barking" squirrels has been too often graphically described by Audubon and others to require more than a passing comment.

The fox squirrel (*S. rufiventer*), which now inhabits almost exclusively the pine forests of the Southern States, is a large species. The body is 14 inches in length and the tail 12. The color is usually a rusty gray or clay color, whitish below and tending on the tail to rufous, margined with black; the top of the head black and the nose and ears white. The colors are, however, exceedingly variable, ranging from gray to deep black. The tail, though large, is less bushy, flatter, and the hair coarser than in the gray squirrel. Some of the varieties of the fox-squirrel extend northward through the mountains to New York and westward to the Dakotas, but have been nearly exterminated in most places and none are quite so large as the typical southern race. In general the habits of the fox-squirrel differ little from those of the gray squirrel, but in the South at least it does not hibernate nor store food, which consists largely of fruits, green corn,

etc. Because of its large size it is much sought for food by the natives.

Of all our squirrels the most abundant and best known in the northeastern United States is the red squirrel or chickaree (*S. hudsonicus*) which, like the others, splits into several subspecies and with related western species occupies British America and the northern half of the United States. In the east the high mountains of North Carolina are the southern limit of its range. The body is eight and the rather thinly haired tail six inches long, the color bright rusty red above, yellowish gray to light gray on the sides and below. Of all the squirrels this species is the most active, noisy and mischievous, constantly tearing over the ground and through the trees, playing, quarreling and chattering with its fellows. In most places it continues active through the winter. They breed and sleep in warm, lined nests in hollow trees or in old nests of crows and other large birds roofed over with twigs, leaves, bark of grape vines, etc.; they also have burrows, used partly as retreats, partly as one of their numerous storehouses for food. Besides nuts, etc., red squirrels feed largely on the seeds of spruce and hemlock, which they extract from the cones with great skill, and they are inveterate robbers of birds' nests, as well as of the farmers' corn-cribs. A remarkable fact is that, though so much inferior in size, this species frequently expels the gray squirrel from certain areas and it is true almost everywhere in the New England and Middle States that it is increasing and the gray squirrel decreasing in numbers.

The ground squirrels (*Tamias* and *Eutamias*) are provided with a pair of large cheek pouches and a well-developed nail on the thumb. The skull is relatively light and narrow, the first upper premolar minute or absent, the tail small and little bushy and the colors striped. The species and races are numerous, all but one Eurasiatic species being North American. The eastern chipmunk (q.v.) or ground hackee (*T. striatus*) is abundant everywhere in open woods from New England to Georgia, a distinct variety replacing it farther north.

Spermophilus is a genus, represented by numerous species in western North America and one in northern Asia and Europe, transitional between the ground squirrels, which they closely resemble in appearance and habits and the marmots. In deed they are ordinarily called striped marmots and by some zoologists are placed in the family *Arctomyiinae*. All have large cheek pouches, well-developed upper premolars and usually short tails; but vary greatly in colors and their pattern. *S. tridecemlineatus* is marked with six light longitudinal stripes alternating with seven rows of white dots on a brown ground. It is an abundant species on the prairies as far east as Illinois and is often wrongfully called "gopher."

Lastly come the flying squirrels, the American species of which belong to the genus *Sciuropterus*. In the absence of cheek-pouches and some other features of their organization these remarkable animals more closely resemble the typical squirrels than the ground-squirrels, but depart widely from these and all other North American mammals in the possession of a densely hairy fold of skin extending along the

sides and connecting the fore and hind legs, forming a parachute which, when extended, supports the animal on its flying leaps from tree to tree. The tail also assists in this function, the dense fine fur spreading at the sides like the vane of a feather. The common species (*S. volans*) is found throughout the eastern half of the United States north to Maine, where it is replaced by a distinct species. See FLYING SQUIRREL.

The squirrels of Europe in general resemble ours, but are less numerous. The common British squirrel, pictures of which are so common, is distinguished by its tufted ears; but our gray squirrel is becoming acclimated in England and is said to be driving away from its haunts the smaller native. Many of the African, and especially those of Borneo and neighboring islands, are remarkable for their large size, conspicuously striped fur, tufted ears or other peculiarities.

Consult Allen, 'Bull. Geol. Geog. Sur. Territories,' Vol. IV (Washington 1878); Allen, 'North American Arboreal Squirrels,' 'American Naturalist' (1899); Bailey, 'Prairie Ground Squirrels,' Bull. Biological Soc. of Washington (1893); Stone and Cram, 'American Animals' (New York 1900).

J. PERCY MOORE,
University of Pennsylvania.

SQUIRREL-CORN, or TURKEY-CORN, a delicate, succulent plant (*Biscutella canadensis*), found in rich woods in North America. It has much dissected leaves, glaucous beneath, rising from the ground and simple scapes from which depend the peculiar, cordate-ovate corollas in racemes, each flower with four petals, the two outer oblong and concave, with short-rounded spurs at the base and parted at the other end to show the much-crested coherent tips of the other two. They are greenish-white tinged with rose-color and are fragrant. The perennial rootstock is creeping and bears many small yellowish tubers, scarred by fallen petioles, which have suggested the common names and also that of turkey-corn.

SQUIRREL HAKE. See HAKES.

SQUIRREL-MONKEY, a small American monkey of the genus *Chrysotrrix*. These are active, tree-hunting, gentle little creatures, with long, rather bushy and squirrel-like tails and tufted ears and are lively and affectionate as pets. A widely familiar species is the Brazilian (*C. sciurea*), which is grizzled gray, with whitish paws and the tail black at the tip.

SQUIRREL-TAIL GRASS. See GRASSES IN THE UNITED STATES.

SRI, PADMA, or LAKSHMĪ, a female Hindu deity, wife of Vishnu. See LAKSHMĪ.

SRINAGAR, *sri-na-gār'*, or **SERINAGUR,** *sēr'i-na-goor'* (signifying "Holy City"), capital of Cashmere, or Kashmir (q.v.), in northern India, in the beautiful valley of the same name, on the Jehlam River, occupies a lofty position, about 5,000 feet above sea-level. It extends about two miles along the river, which, with its windings and the numerous vessels plying upon it, has a very picturesque appearance, but the surrounding low marshes make the climate unhealthful. Near by is the famous Nana Khana Mountain, 23,497 feet in height. It is poorly fortified, although com-

manding a site which permits of making it a great stronghold. Its wooden buildings have been often destroyed by fire and few of them deserve notice. The Jama Masjid, or Great Mosque, celebrated mostly for its enormous dimensions, has a rude dome and spire; another mosque of wood is curiously Chinese in character. There are numerous gardens and a beautiful lake east of the town marks the scene of Moore's 'Lalla Rookh.' Srinagar manufactures attar of roses, shawls, leather, paper, fire-arms etc. It came under the British protectorate in 1846. Pop. about 126,344.

STAAL DE LAUNAY, stâl dâ lô-nâ, **Marguerite Jeanne Cordier**, **BARONESS DE**, French author: b. Paris, 30 Aug. 1684; d. there, 16 June 1750. She was the daughter of a poor painter named Cordier, was brought up at the convent of Saint Louis at Rouen and adopted her mother's name, De Launay. In 1711 she entered the service of the Duchess du Maine as *femme de chambre*. Not long afterward she became amanuensis and companion to the duchess and remained in her household for many years. In 1718 she was implicated in the Cellamare conspiracy and was sent to the Bastille for two years. In 1735 she was married to Baron de Staal. Her 'Mémoires' appeared in 1755 and it is as the author of those frank and lively pictures of the humors of the "court of Sceaux" that she is known to posterity, though she wrote also two comedies and some letters, which latter were published in 1806. Consult Sainte Beuve, 'Portraits Littéraires.'

STABAT MATER, stâ'bât mât'ér ("The Mother stood"), first words and title of a celebrated hymn to the Crucifixion; its authorship is assigned to Jacopone da Todi, a disciple of Saint Francis de Assisi, in the 13th century. It has been set to music by several of the great composers including Palestrina, Pergolesi, Haydn, Rossini and Dvorak. The composition of Pergolesi, for two voices with accompaniment, is the most celebrated, but that of Rossini is the most popular in the concert room. The hymn as given in the 'Breviarium Romanum' office of the festival of the Seven Dolors of the Blessed Virgin Mary (Friday after Passion Sunday) begins:

"Stabat mater dolorosa,
Juxta crucem lacrymosa,
Dum pendebat filius."

STABILLITE, a smokeless powder, invented by Hudson Maxim, possessing the great advantage that no volatile matter is employed in its manufacture and consequently it requires no drying after manufacture, but is ready for immediate use. It was named because it is believed that it undergoes no change by keeping for a great length of time.

STACHYS, stâ'kis, a genus of perennial and annual herbs and a few shrubs of the order *Labiata*. The species, of which there are about 150, are mostly natives of mild climates; a number flourish in the United States. They have simple, opposite leaves, small, white, yellowish, red or purple flowers in axillary whorls or terminal spikes. They are mostly found in low, moist ground, but though several are attractive when in flower they are little cultivated.

STADIUM, a Greek measure of 125 paces, or 625 Roman feet, equal to 606 feet 9 inches English; consequently the Greek stadium was somewhat less than our furlong. It was the principal Greek measure of length. This term was also applied to the course for foot-races at Olympia in Greece, which was exactly a stadium in length. The name was also given to all other places throughout Greece wherever games were celebrated and the name is extended in modern use to cover buildings and equipment for a college racecourse or athletic field.

STADTHOLDER, stât'hôl'dér, a title given in the Netherlands to a governor of a province who was also commander-in-chief of the forces. This title received its special significance in 1580 when the provinces of Holland and Zealand revolted against the authority of Spain and unitedly accepted William, Prince of Orange, as their stadtholder. The prince was assassinated before he was formally invested with this office, but the title was conferred on his son, Prince Maurice, and remained as the hereditary title of the chief of the state until Holland was annexed by France in 1802. This title was finally dropped in 1814 when the Prince of Orange was recalled from England and declared king of the Netherlands by an assembly of notables.

STAËL, Madame de, properly **STAËL-HOLSTEIN**, stâ'êl-hôl'stîn (Fr. stâêl ôl-stân), **Anne Louise Germaine Necker**, **BARONESS DE**, French authoress: b. Paris, 22 April 1766; d. there, 14 July 1817. She was the only child of Jacques Necker, Swiss banker and Minister of Finance to Louis XVI. Her mother was Swiss (see NECKER, SUSANNE C. DE NASSE). Necker's house was the resort of the most distinguished men of the capital; every week on a certain day were assembled in the *salon* of Madame Necker the most eminent scholars of the day, as Marmontel, Raynal, Grimm, Thomas, etc. The encouragement the young girl received in this society and the various excitements which it furnished to her faculties, had an important influence on the formation of her mind. To these she owed that rare conversational power for which she was so remarkable, with that inclination to ingenious, brilliant and striking theories, which appear in her earlier works. Her earliest productions were 'Sophia,' a comedy (1786), and two tragedies, 'Lady Jane Grey' and 'Montmorency.' Her 'Lettres sur les Ouvrages et le Caractère de J. J. Rousseau' (1788), first attracted the public notice. In 1786 she was married to Baron de Staël-Holstein, Swedish Ambassador at the French court, a man much older than herself, whose suit was favored by Madame Necker's desire that her daughter should marry a Protestant.

The breaking out of the Revolution (1789) exercised a powerful influence both on her mind and fate. The first period of her father's service in the ministry (1777-81) brought his family into connection with the great world and public affairs. During Robespierre's ascendancy she exerted herself to save the victims and published a powerful and eloquent 'Defense of the Queen.' After the insurrection of 10 Aug. 1792 she fled in September to her father's house at Coppet in Switzerland, which now became the refuge of the French fugitives. When

Sweden recognized the French republic, her husband was again sent as Ambassador to Paris, whither she returned in 1795. The government of the Directory gave her an opportunity of effecting the recall of some of the emigrants. Barras became her friend, and she acquired so much influence that, on Talleyrand's return from America in 1796, she obtained, through Barras, his appointment to the Ministry of Foreign Affairs. To this period also belong two political pamphlets, '*Sur la Paix*' and '*Sur la Paix intérieure*,' which contain her views respecting the situation of France in 1795 and express the remarkable opinion that France could arrive at limited monarchy only through military despotism. In 1796 appeared her '*De l'Influence des Passions sur le Bonheur des Individus et des Nations*,' which, though characterized by enlightened views, does not contain any complete exposition of the subject. Her connection with her husband, who died in 1802, whose tastes were different and whose talents were inferior to hers, had been from the first marked by coldness, and when she became desirous of securing the property of their children from the effects of his lavish habits, a separation took place; but his infirmities rendering the service of his friends necessary to him, she again joined him. Bonaparte she saw for the first time in 1797, on his return to Paris, after the Peace of Campo-Formio. His brilliant reputation excited her admiration, but this soon gave way to fear and aversion. The danger which threatened Switzerland led her back to Coppet; but when Geneva was incorporated with France she hastened back to Paris, to cause her father's name to be struck from the list of emigrants. But some observations of Necker in his '*Dernières Vues de Politique et des Finances*' (1802) offended the first consul, who caused the work to be attacked in the journals.

Madame de Staël was banished to a distance of 40 leagues from Paris, under pretense that she had given her father false information of the state of France. During her banishment she lived with her father at Coppet, but spent much time in traveling. Her literary reputation was meanwhile increased by her '*De la Littérature considérée dans ses Rapports avec les Institutions sociales*' (1802) and her '*Delphine*' (1802). The former attracted many assailants, among whom Fontanes was the ablest and acutest. Her romance '*Delphine*' contained a faithful picture of herself as she was in her youth—separated from the multitude by genius and sensibility and struggling against the restraints of custom and her sex. In 1803 she made a visit to Germany and lived for about a year in Weimar and Berlin. She paid a visit to Italy in 1805 and the fruit of her journey was '*Corinne ou l'Italie*' (1807), which combines in a happy manner the charms of romance with a faithful picture of Italy. It was finished in France and was no sooner published than she was ordered to quit that country, upon which she returned to Coppet. Here she wrote '*Essais dramatiques*' and finished (1809) her work on Germany ('*De l'Allemagne*'). She then went to France to get it printed, but before it could be published the printed copies were seized by the police and she was again ordered to quit France. It first appeared entire

in London in 1813. This work gave the French the first intimation of the intellectual development of Germany.

Returning to Coppet from France, Madame de Staël was subjected to new persecutions and was forbidden to go farther from her residence than two leagues. But in the spring of 1812 she escaped and passing through Vienna to Moscow, on the approach of the French army went to Saint Petersburg and soon after, in the autumn of 1812, to Stockholm. From Stockholm she went to England, where she was received with the most flattering attention. Here was published her '*Réflexions sur le Suicide*' and '*Zulma et trois Nouvelles*.' After a long exile, described in her '*Dix Années d'Exil*,' she landed at Calais in 1814. After the Restoration in 1815 she returned to Paris and was received with great distinction. She also received from the government public stock to the amount of 2,000,000 francs, due to her father by the treasury at the time of his dismissal from office. Surrounded by a happy domestic circle, esteemed and courted by the most eminent men of the capital, she lived in Paris, with the exception of a short absence, till her death, and until her last sickness she was employed on her '*Mémoires et Considérations sur les principaux Evénements de la Révolution Française*' (1819). By her will it was made known that in 1812 she had been married a second time to a M. de Rocca, a young officer of hussars, who, suffering from wounds received in Spain, had quitted the service and come to reside at Geneva, where she became acquainted with him. See CORINNE.

Consult '*Life*' by Norris (1853); d'Haussonville, '*Le Salon de Madame Necker*' (1882); Lady Blennerhasset, '*Frau von Staël*' (1888-89); Brunetière, '*Evolution de la Critique*' (1890); Schück, '*History of a Marriage in Letters*' (1906); Sorel, '*Madame de Staël*' (1890); Faguet, '*Politiques et Moralistes*' (Vol. I, 1898). Her son edited her works (17 vols.) in 1820-21. Her '*Lettres Inédites*' appeared in 1903.

STAFF, in the army or navy, a body of officers or non-commissioned officers whose duties refer to a body of troops or a fleet as a whole and who are not attached to particular subdivisions. Such officers are called staff officers, while those in command of combatant organizations are line officers. The staff of the army includes the officers of the quartermaster-general's, adjutant-general's, ordnance, medical, engineer (in part), judge-advocate-general's and inspector-general's departments; officers attached to commanding general officers as military secretaries and aides-de-camp, called the personal staff; officers employed in connection with the civil departments at the War Department, chaplains, veterinarians, medical officers of combatant organizations, intelligence officers, etc., and those engaged in recruiting and garrison work, and the general staff of the United States army. See ARMY SCHOOLS; GENERAL STAFF CORPS.

STAFF, in music, the five parallel lines and their intermediate spaces on which the notes, sharps, flats and other musical characters are placed. See MUSIC.

STAFF COLLEGES AND SCHOOLS, military institutions for the advanced instruc-

tion of officers desirous of being placed on the staff of the army. See ARMY SCHOOLS.

STAFF CORPS. See ARMY STAFFS.

STAFFA, stäf'ä, Scotland, a small island of the inner Hebrides, situated seven miles west of Mull. It is celebrated for its basaltic pillars and natural caves, the most noted of which is Fingal's Cave. The island, which is one-half mile in diameter, consists of columnar basalt capped by a shapeless mass. This gives the interior of the caves almost architectural forms. Fingal's Cave extends 227 feet inward and the opening is an arch 66 feet high. The floor is covered with from 9 to 18 feet of water.

STAFFORD, stäf'örd, Henry, duke of Buckingham. See BUCKINGHAM, DUKES OF.

STAFFORD, William Howard, Viscount, an English statesman; b. 30 Nov. 1614; executed on Tower Hill, 29 Dec. 1680. He was the son of the 20th earl of Arundel, the well-known collector of the Arundelian marbles. In November 1640 he was created Viscount Stafford. He was brought up in the Roman Catholic faith and adhered during the civil wars to the royal cause; but after the Restoration he was frequently found in opposition to the court, although he appears never to have played an important part as a legislator. He was singled out by Titus Oates, the contriver of the "popish plot," as one of his chief victims. On 23 Oct. 1678 Oates deposed before the House of Commons that upon the subversion of the kingdom by the Jesuits, Lord Stafford was to have the appointment of paymaster of the army, and on the 30th the accused nobleman was committed to the Tower, with other Catholic peers against whom similar charges had been preferred. After lying two years in prison, he was brought to trial on a charge of high treason 29 Nov. 1680. During a trial of seven days he defended himself by pointing out the weakness of Oates' evidence, so that Evelyn, who was present, thought "such a man's testimony should not be taken against the life of a dog." Nevertheless a verdict of guilty was pronounced by a vote of 55 to 31. He was executed three weeks afterward.

STAFFORD, England, capital of Staffordshire, on the river Sow, 18 miles south of Hanley and 25 miles north by west of Birmingham. The principal buildings include the church of Saint Mary's, which has fine stained glass windows and many interesting monuments; Saint Chads, a fine old Norman church; a stately county hall; a borough hall, containing a museum, and the market hall; hospital, asylum, a Latin school (1550), technical schools and a theatre. The town has extensive tanneries, leather manufactories, and engineering and electrical works. In the neighborhood is Stafford Castle. Many ancient buildings like High House attest to the antiquity of the town. Pop. 23,400.

STAFFORD SPRINGS, Conn., borough in Tolland County, on the Willimantic River and on the Central Vermont Railroad, about 18 miles southeast of Springfield (Mass.) and 18 miles northwest of Willimantic. It is in an agricultural and a manufacturing section of the State. The chief manufacturing establishments are woolen mills, iron works, machine shops, flour-mill, creameries and tobacco works. There

are Protestant Episcopal, Roman Catholic, Congregational and Methodist Episcopal churches. The educational institutions are a public library, founded in 1874, a high school and public and parish schools. There are two banks. Stafford Springs is a favorite resort for health seekers on account of the mineral springs. Pop. 3,000.

STAFFORDSHIRE, stäf'örd-shir, England, a midland county, with an area of 1,128 square miles. The Moorlands is a hilly district at the north, intersected by deep valleys. The surface is mostly undulating. The Trent is the chief river and its tributaries are the Sow, Tame, Blythe and Dove. Few valleys are fertile in the central portion. In the south are important iron and coal deposits. The Dudley and Pottery coalfields contain several hundred collieries and produce large quantities of ironstone. Important copper-pits are found near Warslow, while on the banks of the Dove at the north, colored marble, alabaster, mill-stones and chalk are found. The clay for pottery which makes the Wedgewood ware famous is taken from the "Potteries" district of North Staffordshire, where extensive china and pottery factories exist. The manufacture of various metals is extensive, also leather, silk, wool, linen and sailcloth. The important towns are Stoke-upon-Trent, Burton, Wolverhampton, Wallsall, Handsworth and Smethwick. Pop. 739,000.

STAG. See DEER.

STAG-BEETLE, a beetle of the family *Lucanida*, in which the jaws of the males are greatly enlarged and studded with spike-like protuberances which give them a resemblance to stag antlers. The mandibles of the females are short, of smaller size, and curved, and the club or terminal part of the feelers is four-jointed. These beetles are vegetable feeders and subsist upon the tender leaves and other parts of plants. The larvæ are found in trees, into the substance of which they burrow.

STAGE, The. See THEATRE.

STAGE, The American. See THEATRE.

STAGE COACH. See COACH; OMNIBUS.

STAGE MECHANICS. See THEATRE.

STAGGER-BUSH, an ericaceous shrub (*Neopieris mariana*) found south of Rhode Island in moist, sandy soil, chiefly along the Atlantic Coast. It has a bad reputation for poisoning livestock which may feed on its foliage and giving them the disease known as "staggers." It is a low shrub, rarely four feet high, with erect, wand-shaped, black-dotted branches, bearing alternate, oval leaves, which are shining and leathery and turn to an intense scarlet before falling in the autumn. The flowers are borne in axillary embels, on the under side of the naked year-old branches and are large, white, waxen urns, with five little teeth about the orifice. They bloom in early summer and the shrub is one of the handsomest of its kind.

STAGGERS, one of several varieties of disease in domestic animals, as blind-staggers in horses and cattle, an epileptic disorder primarily affecting the brain and spinal cord. A form of digestive derangement to which horses are especially liable is a kind of gastritis called stomach-staggers. This is a dangerous disease as yet little understood. In the stable the horse

dozes and rests his head in the manger; he then wakes up and eats until the distention of the stomach becomes enormous. The peculiarity of the complaint consists in the total stoppage of digestion and the uneasy feeling of distention, consequent to such indigestion, appears to deceive the horse, whose morbid excitement induces him to continue eating. This he does until the distention prevents the return of the blood from the head and the animal dies from apoplexy, or his stomach bursts. Recovery is rare, except in very mild cases. Grass-staggers is a disorder caused in horses and cattle by eating the loco-weed or crazy-weed (q.v.). It is also known as the loco-disease. In sheep a peculiar kind of staggers occurs which is called gid. See SHEEP.

STAGHOUND. See DOG.

STAHL, stäl, **Georg Ernst**, German physician and chemist: b. Anspach, 1660; d. Berlin, 1734. He studied medicine at Jena and in 1691 was chosen second professor of medicine at Halle and rendered his name famous over all Germany by his academical prelections and his publications. In 1700 he was elected member of the *Academia Curiosorum Naturæ*. His fame procured him the appointment of physician to the king of Prussia in 1716 and he went to Berlin. He was the author of the doctrine which explains the principal chemical phenomena by the agency of phlogiston. This theory was received and supported by some of the most eminent men which Europe had produced. His principal works are '*Experimenta et Observationes Chymicæ et Physicæ*' (1731); '*Disputationes Medicæ*'; '*Theoria Medica Vera*' (1737), and '*Fundamenta Chymicæ Dogmaticæ et Experimentalis*.'

STAHLBERG, stäl'bërk, **Kaarlo Juho**, Finnish statesman: b. 1865. For several years he was the leader of the Finnish National Progressive party in the Diet and in 1914 was elected speaker. Dr. Stahlberg's advocacy of democratic principles brought him under the ban of the old Russian Imperialist régime and at one time he was ordered to be expelled from the Diet by the Russian governor-general. He served as president of the highest administrative court in Finland and also as professor of law in the University of Helsingfors. In July 1919 Dr. Stahlberg was elected president of the new republic of Finland, receiving 143 votes in the Diet against 50 votes cast for Gen. Justus Mannerheim, who had been acting as regent. Dr. Stahlberg has traveled extensively and is well known in European university circles.

STAHR, stâr, **John Summers**, American college president: b. Bucks County, Pa., 2 Dec. 1841; d. 21 Dec. 1915. He was graduated from Franklin and Marshall College, 1867, and at once entered the faculty of that institution, successively being tutor in German and history, assistant professor, professor of natural science and chemistry, financial agent, president pro tem. and since 1890 president of the college. He studied theology, was ordained in 1872 and at one time supplied the pulpit of the First Reformed Church, Reading, Pa. He was a consulting member of the editorial staff of the '*Standard Dictionary*.'

STAIGG, stäg, **Richard M.**, American painter: b. Leeds, England, 1820; d. 1881. He

emigrated to the United States in his 11th year and in early manhood attained consummate skill in painting miniature portraits on ivory. In 1861 he was elected National Academician, and after studying in Paris (1867-69) he abandoned miniature painting for landscape and portraiture in oils. His marines are admirable for color and detail and among his best genres are the '*Sailor's Grave*' (Lenox Library) and the '*Cat's Cradle*.'

STAINED GLASS. See GLASS STAINING AND GLASS PAINTING.

STAINER, stî'nër, **Jakob**, German violin-maker: b. Absam, 14 July 1621; d. 1683. He was apprenticed to a maker of stringed musical instruments at Innsbruck. He learned the secret of the Italian method of constructing violins and won a reputation that passed beyond Germany into Italy and England and lasted for more than a century.

STAINER, stâ'nër, **Sir John**, English organist and composer: b. London, 6 June 1840; d. Verona, Italy, 1 April 1901. At seven he became a chorister in Saint Paul's Cathedral; in 1856 Sir Frederick Ouseley appointed him organist of the newly-founded Saint Michael's College at Tenbury, and four years later he became organist of Magdalen College, Oxford. From 1863 till 1872 he was university organist, and from the latter year until his resignation in 1888 held the post of organist in Saint Paul's, London. In this position he achieved great success and contributed much to the improvement of the musical part of the service in the cathedral. In 1881 he succeeded Sir Arthur Sullivan in the principalship of the National Training School, and in 1882 became inspector of music in the elementary schools of England. He was professor of music in the University of Oxford from 1889 till his resignation in 1899. He was knighted in 1888. He was a composer of considerable ability, his principal compositions being cantatas entitled '*The Daughter of Jairus*' (1878); '*Saint Mary Magdalen*' (1883), and '*The Crucifixion*' (1887), and many anthems, organ pieces, etc. He published various musical primers, a '*Dictionary of Musical Terms*' (with W. A. Barrett), and a valuable work on 15th century music entitled '*Early Bodleian Music: Dufay and his Contemporaries*.'

STAINES, stânz, England, a town in Middlesex, on the Thames, six miles southeast of Windsor. Runnymede, Egham and Cooper's Hill are interesting suburbs. Inigo Jones and Rennie, two of England's greatest architects, are remembered by the church of Saint Mary's (1631), and the bridge across the river (1832), respectively their works. The Roman Catholic Gothic church dates from 1868. The industrial works include breweries and mustard mills. The garden-markets and race-course are interesting features. Pop. 6,688.

STAIR, Lord. See DALRYMPLE.

STAIR, a succession of steps affording means for a person on foot to get from a lower to a higher level. There are two main forms of this, one composed of a series of solid blocks generally touching one another at one edge, as when a series of squared stones are built into a wall at either end, their small surface of junction merely steadying them; and the more com-

mon sort, in which two sloping beams, planks or metal girders, called string pieces or strings, support a series of horizontal planks, slabs of marble or slate, or plates of metal called treads. The above are the essentials of a stair. The riser which stands for the vertical distance from one tread to another may be left open, or may be filled by a light board, a piece of open-work cast iron or the like. In the case of a stone step the tread is the uppermost surface and the riser the front—the surface turned toward the person who is ascending.

There is a marked distinction between the straight and the winding stair. In a straight stair all the steps are called fliers and the tread of each is of the same width from end to end. In the winding stair the steps are called winders and the treads are much narrower at one end than at the other. The typical winding stair is the spiral or corkscrew stair (in French called *à colimaçon*, snail-like). These are commonly built into round towers, the walls of which support the steps, but it is feasible to build them of wood or iron, and in modern libraries and other places of storage, very light spiral stairs are built for easy access to balconies, galleries and upper floors, as in the stack-room for books or other place of deposit or storage.

A stair may be made up of several short stairs called usually flights. Thus in the case of a rather lofty story, there may be one or even two landings in the height from floor to floor, and, therefore, two or even three flights. If these landings give to the stair a change of direction of 90 degrees, so that a person ascending and going northward suddenly turns eastward or westward, the platform is called a quarter-pace (sometimes quarter-space). If the change of direction is of 180 degrees, the person ascending reversing his direction as from north to south, the word half-pace (half-space) is used. A combination of these methods is also used, as where a platform is associated with some winders; the platform being then nothing but a tread much wider than the others. This is a very objectionable plan, as being dangerous for persons not acquainted with the stair.

The height of the riser and the width of the tread are matters of great importance. Rules exist for fixing these, and it is generally considered that the riser and tread must be taken together. Thus, if it be held that each tread-and-riser should measure 18 inches, then the riser may be $6\frac{1}{2}$ inches high, the tread $11\frac{1}{4}$ inches wide. This is often expressed by the formula, a riser $6\frac{1}{2}$ inches, a run of $11\frac{1}{4}$ inches, or by the phrase, the rise and run are to each other as $6\frac{1}{2}$ to $11\frac{1}{4}$. In modern buildings of no great cost or elegance the stairs are often very much steeper than this; and the proportions may even be reversed, or nearly so, in the case of a flight rarely used, as from the top floor to the roof.

The stair is often an architectural feature of some importance. In the interior a large hall is sometimes devoted to it, and the stair itself is a principal part of the decoration, perhaps passing along three sides of this hall, seeming to cling to the wall as it ascends, leaving below an open floor of considerable size which may be treated more or less as a sitting-room, and at the top communicating with a gallery. This gallery may be a highly architectural mem-

ber, being treated with columns to support the roof. The objections to this treatment of a stair are the great amount of space occupied and the opening of so much of the interior to drafts of air and to ready communication of fire. It should only be used where the building is wholly fireproof. It leads to great expense in building the stair of marble, lining the walls with the same or an equally costly material and roofing the whole with an architectural dome or coved ceiling with or without a sky-light. The tendency in recent times is to use elevators in buildings of all kinds, public and private, and in consequence of this the stair seems to be considered sometimes a mere piece of utility and for that purpose made as compact as possible; while in another building not more costly and splendid it will be treated in the way described above. It is worthy of notice that any building in which it is expected to give stately entertainments, the stair-case, or hall, which encloses the stair, will be treated in a more stately way, and this because of a tradition that the persons of a large assemblage will seek the halls and stairs, perhaps for more space, perhaps for fresh air. Thus, in an opera house, the stair is a very important feature.

Out-of-door stairs are seen on city tenements and apartment houses as fire-escapes, but they do not often exist in connection with classical or neo-classical architecture. They have great picturesqueness of effect and are associated with mediæval architecture—both northern and southern—and with the rough wooden buildings of Switzerland and Tyrol.

The term stair is not often used to cover the broad flight of steps leading up to a portico, nor for the steps of a front door when they do not exceed 10 or 12 in number; nor yet for those in a terraced garden. For such out-of-door flights of steps the French term *perron* may be used and is perfectly descriptive of the thing; no correlative term exists in English except the local term used in New York City and vicinity: stoop.

RUSSELL STURGIS.

STALACTITE and **STALAGMITE**, deposits of lime hanging from the roof (stalactites) or rising from the floor (stalagmites) of a cavern. Stalactitic formations occur chiefly in long and more or less fantastic masses suspended from the roofs of caverns in limestone rocks. Stalactites appear to be continually forming; water containing carbonate of lime held in solution by carbonic acid, trickling through crevices in the roofs of the caverns, gradually during its exposure to the air loses its carbonic acid and consequently deposits its carbonate of lime; the water passing over the portion first deposited gradually adds to it, and eventually gives the carbonate of lime its great length and stalactitic character. The flatter deposits, called stalagmites, are formed on the floor of the cavern by the water there depositing that portion of its carbonate of lime which is not separated during the formation of the stalactite. They sometimes occur as cones rising to meet the stalactites in the form of large pillars, and sometimes form flat crusts over the bottoms or sides of a cave. Stalactitic carbonate of lime is met with in the veins of lead ore in Durham and Northumberland,

England. Caverns are sometimes nearly filled with these deposits, which in some cases are of very large dimensions. Oriental alabaster (q.v.) and Mexican onyx are formed as stalagmitic crusts, and consist of calcium carbonate. Among striking examples of stalactites and stalagmites are those of the Luray and Mammoth caves (qq.v.) in the United States; those in the cavern at Castleton, Derbyshire, England, and in the Isle of Skye; in the grotto of Antiparos in the Grecian Archipelago; in the Woodman's Cave in the Harz, Germany; at Auxelle, France; and the most important of those at Adelsberg, Austria-Hungary. Stalactites of iron sulphide, marcasite, are also known. By oxidation of the sulphide, they may be altered to limonite, forming the so-called pipe ore of certain Missouri iron deposits.

STALEY, Cady, American civil engineer and educator: b. Minaville, N. Y., 12 Dec. 1840. He was graduated at Union College in 1865, and after a period as a gold prospector in the Rocky Mountains he was a civil engineer engaged in the construction of the Central Pacific Railroad. He became associated with the faculty of Union College in 1867, was appointed professor of civil engineering in 1868, and in 1876-86 he was dean of that institution. He was president of the Case School of Applied Science, Cincinnati, in 1886-1902. Author of 'Strength of Materials and Stability of Structures' (1876); and joint author of 'The Separate System of Sewage' (1882; 3d ed., 1899).

STALIMENE. See LEMNOS.

STALKER, stāk'ér, James, Scottish Free Church clergyman: b. Crieff, 21 Feb. 1848. He was educated at the universities of Edinburgh, Halle and Berlin, and at New College, Edinburgh. He held pastorates at Kirkcaldy and Glasgow, 1874-87; delivered the Lyman Beecher lectures on preaching at Yale University, 1891; was Cunningham lecturer in 1899, and has been professor of church history in the United Free Church College, Aberdeen, since 1902. Among his many publications are 'The Life of Jesus Christ,' 'The Preacher and His Models,' 'The Seven Cardinal Virtues,' 'The Two Saint Johns,' 'The Christology of Jesus,' 'Life of St. Paul,' 'Imago Christi,' 'Trial and Death of Jesus,' 'The Seven Deadly Sins,' 'John Knox,' 'How to read Shakespeare,' 'Poets and Poetry of the Bible,' etc.

STALL, Sylvanus, American Lutheran clergyman and author: b. Elizaville, Columbia County, N. Y., 18 Oct. 1847; d. 6 Nov. 1915. He was graduated at Pennsylvania College, Gettysburg, 1872, and studied theology there and at the Union Theological Seminary in New York. He held Lutheran pastorates from 1874 to 1888, and was associate editor of the *Lutheran Observer* from 1890. He was for years statistical secretary of the general synod of the Lutheran Church and published 'Stall's Lutheran Year Book and Historical Quarterly' (1884-88). His other publications include 'How to Pay Church Debts' (1880); 'What a Young Boy Ought to Know' (1897); and the three other volumes of the 'Purity Series,' concluding with 'What a Man of Forty-five Ought to Know' (1901).

STALL, a fixed seat in a church, intended for the accommodation of one of the choristers or of the clergy, and therefore usually in the choir. Much the most common arrangement is to have the stalls in rows on the two sides of the choir, the occupants of the stalls looking inward toward the axis of the church and therefore toward the altar or the space immediately behind or before it. Such a fixed seat forming one of a group will naturally be enclosed at the back and sides, and it is customary to have two rows of stalls, an outer one set immediately on the floor or with a few inches elevation in order that a wooden floor may be put above the stone floor of the church, and a second row behind, perhaps two steps higher. Where a row of stalls is very long there may be an opening or more openings than one in the front row, made by the omission of a seat, and intended for access to the back row.

As the occupant of a stall sometimes sits and sometimes stands for a length of time during the service, it is common to arrange a hinged seat easy to lift and to lower again, and made heavy so as to be firm. Such a seat is usually carved out of a solid mass of heavy wood, the boss underneath which gives it weight and balances it on the hinges, being often an elaborate representation of a cluster of leaves, a human figure or a group of several figures, or a monstrous animal. Such bosses are called misericords or sometimes misericeres.

The most elaborate stalls known are those of the cathedral of Amiens, magnificent joinery and carving of about 1510.

RUSSELL STURGIS.

STALLO, John Bernard, German-American jurist and scientist: b. in Grand Duchy of Oldenburg, Germany, March 1822; d. Florence, 5 Jan. 1900. He received a liberal education in Germany and came to America when 16. Was professor of Latin and Greek in Saint Xavier's College, Cincinnati; was also proficient in English, German, Dutch, French, Spanish, Italian and Hebrew. After two years at Saint Xavier's he was made professor of Latin in Saint John's College, New York, and while there studied law. He returned to Cincinnati in 1847 to practise law, and sat upon the Common Pleas bench of Hamilton County in the 50's. In 1885 Judge Stallo was appointed Minister to Italy by President Cleveland, but upon the election of Harrison he resigned and lived in Florence until his death. The last 15 or 20 years of his life were largely devoted to the study of philosophy. He published 'General Principles of the Philosophy of Nature,' 'The Concepts and Theories of Modern Physics,' and 'Abhandlungen und Briefe.'

STALWARTS. See REPUBLICAN PARTY.

STALYBRIDGE, stāl'i-brīj, England, in the counties of Lancaster and Chester, about five miles east of Manchester, on the Tame, stands in a barren district on slopes rising from both banks of the river. The public buildings include the town-hall, free library, several churches and post office. The manufacture of cotton goods is considerable, occupying many thousand hands. Besides, there are foundries,

machine shop and millwright works. The importance of the town dates from 1776. Pop. 27,673.

STAMBOUL, stām-bool'. See **CONSTANTINOPLE**.

STAMBULOFF, stām-boo'lof, **Stephen Nikolof**, Bulgarian statesman: b. Tirnova, 1853; d. Sofia, 18 July 1895. He took part in the rising of 1875-76, and as an office-holder during the occupation by the Russians, following the War of 1878, became prominent as a leader of the radical party in the new national assembly. He was a conspicuous member of the regency which followed the abdication of Prince Alexander, strongly opposed to the adherents of the Russians, and when he became Premier in 1878, after the election of Ferdinand, ruled with scant regard for prince or legislature. He was forced to retire in 1894; his death the next year was the result of an attack by assassins.

STAMFORD, stām'förd, Conn., city in Fairfield County, on Long Island Sound and Mill River, and on the New York, New Haven and Hartford Railroad, about 22 miles southwest of Bridgeport and 30 miles northeast of New York. The harbor is large enough for large Sound vessels. The city has regular steamer connection with New York, and electric lines extend to all the nearby cities and towns. Stamford was settled in 1641 by a colony from New Haven. An Indian village named Rippowam had existed here, but the name was changed in 1642. It was incorporated as a borough in 1830, and in 1894 was chartered as a city. The surrounding country is devoted mainly to agriculture, but the city has large manufacturing interests, and is the commercial centre of an extensive region. The chief establishment is the Yale and Towne Manufacturing Company, which regularly employs about 2,500 persons. Other manufactures are extracts, type-writing machines, woolen goods, lumber, hats, shoes, machine shop products, pottery, dye-stuffs, patent medicines, chemicals, hardware and wagons and carriages. The government census of 1910 gives the number of manufacturing establishments as 86; the amount of capital invested, \$11,926,000; the cost of material used annually, \$3,704,000; and the value of the product, \$8,740,000. There are a number of small parks in different parts of the city; three in the residential section. The water supply comes from Trinity Lake in New York State. There is an excellent sewerage system and a paid fire department. There are a large city hospital, Saint John's Hospital and Home, and several private sanatoriums. The educational institutions are a high school (new building erected in 1895), the diplomas from which entitle the holders to entrance to several universities and colleges; nine large elementary schools, one large parish school, the Catherine Aiken School for girls, the Betts Academy, founded in 1838, for boys; Misses Low and Heywood School, the King School and the Manor School at Shippan Point. The Ferguson Library is housed in a fine building. The banks have a combined capital of approximately \$1,000,000. The government as at present constituted is administered under a charter which provides for a mayor and a common council, elected biennially in even years. Appropriations

are in charge of a board of appropriation. The population of the city in 1910 was 25,138, but the town of Stamford has 28,836 inhabitants. The 1917 estimate is 32,000 for the city and 36,000 for the town.

STAMFORD, England, in the counties of Lincoln and Northampton, on the Welland, 12 miles northwest of Petersborough. The main buildings are Saint Mary's Church (13th century), All Saints, Saint Martin's, Saint John the Baptist's (15th century), town-hall, corn exchange, assembly and club rooms, literary institute, Browne's hospital (15th century), school and charitable institutions. The manufacture of agricultural implements and breweries are the chief sources of industry and trade. Pop. 8,229.

STAMMERING, a defect of speech due to failure in co-ordinate action of certain muscles and their appropriate nerves. It is analogous to some kinds of lameness, to cramp or spasm, or partial paralysis of the arms, wrists, hands and fingers, such as is sometimes attendant upon certain exercises; for speech is a muscular act involving the co-ordinate action of many nerves and muscles.

The words stammering and stuttering practically denote the same infirmity, although stuttering is now limited more or less to the futile repetition of sounds, while stammering covers the whole defect—hesitation, glide, stop, holding on to the sound, as well as repeating it. Because stammering is proved to be pretty widespread in Prussia, Great Britain and its colonies, and the United States, and uncommon in Italy and Spain, the question suggests itself whether languages of Teutonic origin are not more apt to generate it than languages of Latin origin. This chief of the imperfections of speech may be hereditary, and it may be acquired by imitation. Like yawning, it is infectious. It may be the abiding result of mental strain or shock. Fever may bring it on, epilepsy, hysteria, or any serious nervous affection or strong emotion, temporary failure of health, any excitement, or even soreness of the mouth. It rarely shows itself earlier than at four or five years of age. It usually begins in youth, but may be produced at any later age. A much larger proportion of males than of females stammer. Stammering used to be ascribed exclusively to the organ of articulation, the mouth; to faulty setting of the teeth or the jaws, to the largeness and thickness of the tongue, its weakness of movement, its excessive vigor, etc. At present in the research for the cause and cure of stammering full account is taken of the vocal cords or cushions and the vocal chink.

Stammering occurs in the mouth, the organ of articulation. Its proximate cause is always in the larynx, the organ of voice. Sometimes the lungs, the organ of breathing, complicate the uncertainty and unsteadiness of the vocal cords and the vocal chink in the larynx. A current of air, variously shaped by the mouth as a whole, is what is called a vowel. A stammer on a vowel can only take place in the vocal chink, rima glottidis. The sounds called consonants are produced by closures, more or less firm, of contents of the mouth. Thus, *b*, *p*, *m*, *w*, by the closure of the two lips; *f*, *v*, of the lower lip and upper teeth; *g* soft and *sh*, of the teeth; *l* and *th*, tongue and upper teeth; *t*, *d*, *n*,

s, z, y, tip of the tongue and fore gum; *g* hard and *k* back edges of the tongue and back gum. Stammering may occur at any of these six closures. It is, perhaps, most apt to occur at the labials *b, p*, the dentals *d, t*, the gutturals *g* hard, *k*, because for these the closure is firmest. The stammerer has no difficulty in setting lips, teeth, tongue and gums against each other as required. His difficulty is to relieve the closure, to get at the vowel which is to follow the consonant. The tongue, for example, will not part with the teeth — seems to cling spasmodically to them — because the current of air, the vowel, does not come at the proper instant through the vocal chink to relieve it. In this way the three observable modes of stammering are explained. If the vocal chink does not open soon enough there is a stop stammer; if it flutters, there is a stutter; if it opens too soon, there is a glide stammer. But, further, the lungs expand and contract by nervous and muscular energy; and, besides, the muscular and nervous machinery of the breastbone, ribs, midriff and upper abdomen are all concerned in that expansion and contraction. These complicated and delicate bellows which supply air under pressure to the organ of voice may be defective, out of order, misused. Their working is to be closely observed in the case of each stammer. Stammerers, as a rule, breathe badly. They constantly try to speak when their lungs are empty.

Stammering can be cured. It often disappears gradually without special effort at cure, through an improvement in the general health and especially of the nervous system. Improvement generally takes place as age advances. In some cases resolute endeavor is demanded. A waving motion of the arms, time kept to a baton were favored as cures at one time. They were on the lines of the musical methods of cure — intoning, chanting, singing — which were based on the fact that most stammerers can sing without difficulty. The stammerer should be taught to regulate the breath, and he should work for a habitual use of the chest voice — for deeper, steadier vibration of the vocal chords — since stammering usually occurs with use of a head voice. The stammerer should take exercise in a chest voice, on the sounds (seldom vowels) at which a stumble is apt to be made.

STAMP ACT, an act for regulating the stamp duties to be imposed on various documents. In 1765 George Grenville, chancellor of the English exchequer, proposed a bill for taxing the colonies through a stamp duty. No serious opposition was expected. But the measure aroused great excitement in America as an attempt at taxation without representation. In the United States, a Stamp Act congress consisting of delegates from all the colonies except New Hampshire, Virginia, North Carolina and Georgia, met at New York 7 Oct. 1765, and adjourned 25 October. The action of this congress consisted of an address to the king, petitions to Parliament and a declaration of the rights and grievances of the colonies. It protested that the colonies could only be taxed by their own representatives in the colonial assemblies; claimed the inherent right of trial by jury, and declared the Stamp Act to have a manifest tendency to subvert the rights and liberties of the colonies.

STAMP COLLECTING. See **PHILATELY**.

STAMP-DUTY. See **DUTY**; **TAXATION**.

STAMP-MILL, a crushing mill or machine for pulverizing ores and rocks. In Western mining camps the stamp-mill is usually worked by water power. See **MINING**.

STAMPING OF METALS. See **DIES AND DIE MAKING**.

STAMPS, Postage. The boldness of conception in suggesting a penny (two cents) postage for Great Britain for letters of half an ounce showed a broadness of mind well worthy the title of "Sir" it brought later on Mr. Rowland Hill. Railroads, it is true, were making travel both easier, cheaper and more rapid, but they were few and postal delivery through all the United Kingdom still meant transportation largely by coach and frequently over roads that were bogged in wet weather (and England, then as now, had a rainy climate). Rates for single letters at that time were as follows for delivery in England or Wales from any post office to any place:

Not exceeding 15 miles from such office.....	4 pence.
Between 15 and 20 miles.....	5 "
Between 20 and 30 miles.....	6 "
Between 30 and 50 miles.....	7 "
Between 50 and 80 miles.....	8 "
Between 80 and 120 miles.....	9 "
Between 120 and 170 miles.....	10 "
Between 170 and 230 miles.....	11 "
Between 230 and 300 miles.....	12 "

Added to this was another penny on each single letter for every 100 miles over 300, also one penny for postage and sometimes "toll-fees." A letter from Kirkwall to Southampton called for an expenditure of one shilling and six pence; to London nine pence plus another penny for postage; to Cork, Ireland, cost one shilling and three pence. These sums were for a single sheet of paper, two sheets costing double. Under such conditions came Hill's Uniform Penny Postage plan. The system of franking suggested did away with the great cost of "collection" and frequent loss on refusal of payment on the part of the addressee. The cost of production and sales of penny stamps was comparatively infinitesimal, and this fact, of course, permitted its success, also the enormous growth numerically of the patronage. Before the introduction of the reform the post office handled (in 1839) 75,907,572 letters; letters for the following years were:

1840.....	168,768,344	1880.....	1,176,423,600
1850.....	347,069,071	1890.....	1,705,800,000
1860.....	564,002,000	1900.....	2,323,600,000
1870.....	862,722,000	1910.....	2,947,100,000

The term "postage-stamp" is, of course, something of a misnomer that has crept into the English language. It is no *stamp*. What we call the "post mark" is a *stamp*. When the adhesive "stamp" was first introduced it was known as a "label," and to the philatelist it remains a "label" to this day. As a discussion of a subject presupposes some knowledge of the terms used by the expert it would be well to explain some of the terms used by the philatelist. We will quote a few in part from Fred J. McVillev's 'Chats on Postage Stamps.'

Terminology.—**ALBINO.**—An impression made either from an uninked embossing die, or from a similar ink die, under which two

pieces of paper have been (inadvertently) placed, the upper one alone receiving the color.

BISERT.—A term applied to a moiety of a stamp, used as half the value of the entire label.

BLEUTÉ.—This word implies that the blueness of the paper has been acquired since the stamp was printed, through a chemical reaction.

BLOCK.—An unsevered group of stamps, consisting of at least two horizontal rows of two each.

BOGUS.—Any stamp not designed for use.

BURELÉ.—A fine network forming part of the design of stamp, or covering the front or back of entire sheet.

CHALKY.—Called also *chalk-surfaced*. An overlay on the paper's surface of a coating of chalk or similar substance. It renders the print liable to rub off if wetted; in combination with a doubly-fugitive ink, this renders fraudulent cleaning impossible.

CLICHÉ.—The ultimate production from the die, and of a number of which the printing plate is composed.

COLOR TRIALS.—Impressions taken from a plate in various colors, so that a selection may be made.

DUTY-PLATE.—Many modern stamps are printed from two plates, one being the same (*key-plate*) for all values, the other differing for each denomination; this latter is the *duty-plate*.

ENTIRES.—When used in describing an adhesive stamp, as being "on entire," this term implies the stamp is on the envelope or letter as when posted.

ENVELOPE STAMP.—A stamp belonging to and printed on an envelope.

ERROR.—An incorrect stamp—either in design, color, paper, etc.—which has been issued for use.

ESSAY.—A rejected design for a stamp; in the French sense also applied to proofs of accepted designs.

FUGITIVE.—Colors printed in "singly-fugitive" ink suffer on an attempt to remove an ordinary ink cancellation; but if in "doubly-fugitive" ink it was thought that the removal of *writing-ink* would injure the appearance of the stamp.

GRILLE.—Small plain dots, generally arranged in a small rectangle, but sometimes covering the entire stamp, embossed on certain issues of Peru and the United States. Done to break up the fibre of the paper and allow the ink of the postmark to penetrate it and make cleaning impossible.

GUILLotine.—A perforating machine that punches a single straight line of holes at each descent of the needles.

GUMPAP.—Term of opprobrium applied to a stamp issued for sale to collectors and not to meet a postal requirement.

HEAD-PLATE.—See *Duty-plate*.

IMPERFORATE.—Stamps which have not been *rouletted* or perforated.

KEY-PLATE.—See *Duty-plate*.

MINT.—A term showing that a stamp, or envelope, etc., is in exactly the same condition as when issued by the post office—unused, clean, absolutely unmutilated and with all the original gum.

OBLITERATION.—Any mark used in cancellation.

PAIR.—Two stamps joined together as when originally printed.

PANE.—Entire sheets of stamps are frequently divided into sections by means of one or more spaces running horizontally or (and) vertically between similarly sized groups of stamps; each section being termed a *pane*.

PLATE.—A sheet of metal with the stamps engraved on it, also a group of clichés.

PLATE NUMBER.—The consecutive number of each plate, appearing on the margin of the plates and (in some of the British series) on the stamps themselves.

PRE-CANCELLED.—Two or three countries have adopted the system, to save time in the post office, of supplying sheets of stamps cancelled prior to use.

PROOF.—An impression, properly in black, from the die, plate or stone, taken to see if the design, etc., has been properly engraved or reproduced. There are *plate-proofs* as well as *die-proofs*.

PROVISIONAL.—A make-shift intended to supply a temporary want of the proper stamp, which may have been unexpectedly sold out, or may not have been supplied owing to lack of time.

SURCHARGE.—An overprint altering the face value of a stamp, or confirming it in the same or a new currency.

TRIALS.—Impressions from die, plate, stone, etc., taken to ascertain if the design be correct, or to assist in the selection of a color.

TYPE.—A representative common design, as distinguished from "variety," which indicates slight deviations therefrom.

History.—Adhesive stamps are said to have been invented by James Chalmers of Dundee, Scotland, in 1834, and came into use 6 May 1840, when Parliament had sanctioned their use. M. de Villayer, of Paris, in 1653, invented letter covers or wrappers with a distinctive mark which he sold for two sous (one English penny) as a frank for his collectors who took them from the letter-boxes he established in the chief thoroughfares and delivered to destination addressed on them. In 1839 Parliament passed the Uniform Postage Act. Mr. (later Sir) Henry Cole was secretary of the committee (1838) appointed to inquire into the best methods of charging and collecting postage. Stamped covers, stamped paper and stamps to be used separately were suggested as plans. Cole got Mulready, the artist, to draw a design for the envelope. On passage of the act he got together Wyon the medal sculptor, Henry Corbould the artist, and Frederick Heath the engraver, and they devised the first penny postage stamp. Heath engraved the world-famous Victoria head and the lettering and the back-ground was "engine-turned," the curves made with a Rose engine. To Messrs. Perkins, Bacon and Company, London printers, was given the task of printing the "labels" to be impressed by the "Perkins mill and die process," which has been used ever since on art stamp work. Envelopes, covers, and adhesive stamps were all issued simultaneously on 1 May 1840 but not to be used till 6 May; £2,500 worth were sold the first day, and Cole reported that "about half the letters"

mailed were *stamped*. Six more days clearly proved it was *labels* (stamps) the public almost unanimously preferred, and the Mulready allegorical envelope enjoyed less than 1 per cent of the sales, so was soon retired. And thus originated the first postage stamp. Lecky the historian wrote: "The Stamp Act . . . must be deemed one of the most momentous legislative acts in the history of mankind."

The first postage stamp was the black impression and found a serious drawback; it was printed in a *fast* ink, and the consequence was that those dishonestly inclined washed out the "obliteration" (cancellation) marks and used the stamps over again. In nine months red stamps from this die were produced in a *fugitive* ink. And thus the first stamp (black one penny) naturally became a rarity for collectors early on account of its brief career. It is a source of wonderment how the British got along for such a prolonged period without stamps of any denomination but those of one penny and two pence. For a considerable time "check" letters were used on the four corners of the postage stamp. The first foreign stamp was that issued by Brazil in 1843 (the "bull's eye" which lasted one year), Belgium and France following in 1849. To meet the request of some high officials "cameo" embossed adhesive stamps with the Victoria head were produced to forbid forgery which line engraving had not done. They were done in three valuations (a shilling, two pence and six pence) for use (1847) of the rates to the United States, France, etc. These took 24 processes instead of the former one. Silk threads were embodied in the paper in the shilling and the sixpenny. The issue died out within a decade.

Odd Stamps.—The "albino" stamp is an "error"; it is impressed with an uninked embossing die. An "Omaha" one dollar stamp uses Dunthorne's etching of MacWhirter's painting 'The Vanguard' to which the United States post office gave the title "Western Cattle in a Storm." Little doubt but some artist imposed on Uncle Sam's innocence of art and accepted the drawing as original. Some stamp specimens have their colors inverted through wrong "feeding" in the press. There are many such odd stamps, but they belong to the subject of philately and stamp collecting.

Commemorative Postage Stamps.—These form a series of historical interest but were issued for postal service. A few might be mentioned here. In 1890 appeared the jubilee "Uniform Penny Postage," later followed the American Exposition, the Newfoundland (1897), "Queen Victoria Diamond Jubilee" stamp, the Canadian "Founding of Quebec" series, the United States Columbian World's Fair series and the exposition stamps "Omaha," "Pan-American," "Buffalo," "Panama," etc. A lugubrious reminiscence is the issue by Russia in 1913 of the stamps in honor of the House of Romanoff! In commemoration of the Great War of Europe the Germans used on some of their adhesives the word "Belgian," lacking foresight of the outcome, not to mention misstatements on freshly issued labels for their colonies, which tell volumes of the Teutonic misconception of her future. The United States three-cent lilac stamp of quite recent memory should act as a reminder of our 50 per cent rise in

letter postage during the war period. Speaking of United States postage stamps we should not omit to mention the fact of Uncle Sam not using the effigy of any President or other august personage until after death.

Forgeries, Fakes, Etc.—Naturally, the postage stamp, being a kind of government paper currency, forging of the specimens became an occult art and practice. The first of these false labels came to light as early as 1840, four months after the government's first issue. By 1863 there already existed a sufficiently numerous quantity to justify the compilation and publication of a work detailing and describing these pseudo franking labels. The first of these worthies to accelerate labels in commercial quantities was a Zürich, Switzerland, forger. His specialty was Swiss Cantons, Modena, Romagna and others, and his agent in Basle obtained *steep* prices for his wares. Next cropped up a Brussels citizen with false Provisional Parma, Modena, Naples and Spain stamps of good execution. From Brunswick and Leipzig issued Danish "essays" and other species of fakes. Very soon thereafter Stourton informed his readers that Glasgow, Manchester, Newcastle, London, Hamburg and New York were competing with the government output. Swiss and Belgian forgers multiplied the number. Bona-fide producers of "facsimiles" were placing such words as "facsimile" or "Falsch" on their colored reproductions of stamps that were printed to aid collectors in identifying specimens of the lesser-known varieties, but the dishonest utilized the opportunity by expunging the fake declaration and selling them as genuine. And the controversy goes on as to whether they do not produce greater harm to the collector than good. Earée's 'Album Weeds' and other works no doubt aid to sift the *chaff* to some extent in the encounter with the great multitude of fakes. Forgeries are produced by *altering* originals as well as by making "facsimiles." Usually the first are termed "fakes" and the latter "forgeries." Strangest of the pseudo stamps are the "bogus" ones, designed and invented fiction on paper, the like of which has never been devised by any government but are pure figments of the illicit designer's genius. A great "haul" appears to have been made before 1898 (the date when the fraud was discovered) by forgeries of the green one shilling stamp, 1865 type, with uncolored corner letters. They were used on telegrams and, therefore, had escaped official scrutiny, and unknown masses had gone into circulation. The number of Spanish counterfeits was so large and so persistent that the government had to issue fresh series nearly every year; the Naples and Neapolitan States were bad sufferers. The Indian one rupee stamp, issue 1882-88, had a clever counterfeit, but the culprit was caught. A later fraud is the raised valuation mark on British colonial genuine stamps. While such forgeries and fakes are made at the expense of the government, more have been created with a view of mulcting the collector. Of such are the 10-shilling and the one-pound (on a large anchor) 1878-83 issue imitations done in 1903, apparently, on fiscal water-marked paper, but quickly discovered. A recent fake is a copy of the 1875 twopence halfpenny stamp which was "minted"

by the British government with an *error* in the corner-lettering LH-FL instead of LH-HL in the last stamp (12th) of the eighth horizontal row, and, being rare, it tempted fraudulent reproduction. The detection of some forgeries is exceedingly difficult. A well-known philatelist informed the public of a sure (but not advisable) test for differentiating government Cashmere stamps from fakes. His suggestion was to place the label of indeterminate character in water—if the color is fast it is fake, if the water dissolves the color and leaves the paper blank it is genuine. Some sets of forgeries have been self-acclaimed counterfeits, such as the United States of America large 1875-95 stamp for use on newspapers of one cent to \$100 valuation. These counterfeits had the words "Falsch" and "Facsimile" printed on each of them, as did some early Japanese frauds (the latter in microscopical characters). Of the popularity of certain issues with the fraternity of counterfeiters might be mentioned the fact that the Canton Basle 1845 has 17 counterfeit varieties done by various methods and with varying degrees of ingenuity. The "double Geneva" can boast of at least 15 dishonest rivals, its value "entire" being about \$370 unused and about \$135 used. Governments (but only a few, be it to their credit) have supplied the fakers with discarded dies and plates "for reprints" to wreak their worst on innocent collectors or even to make counterfeits for themselves. The United States, in 1875, had new dies made for the 1847 five cents and 10 cents issues for those not in hand so as to produce a complete series of its issues. Their difference is distinguishable, but are they "counterfeits?" The Rumania government, to fill a foreign demand, had three new die types produced for sale as the rare July 1858 stamps. The official fraud was not discovered for a number of years.

STANCHFIELD, John Barry, American lawyer and politician; b. Elmira, N. Y., 13 March 1855. He was graduated at Amherst College in 1876, later studied law at the Harvard Law School, and was admitted to the bar in 1878. He engaged in practice at Elmira, and in 1878-85 was a partner of David B. Hill. He was district attorney of Chemung County in 1880-85; mayor of Elmira in 1886-88 and a member of the State assembly in 1895-96. After his defeat as Democratic candidate for governor of New York in 1900 he engaged in law practice in New York. He was defeated as Democratic candidate for United States senator in 1901. His career as a lawyer has been markedly successful. In 1915 he was a delegate to the New York State Constitutional Convention.

STAND-PIPE, (1) in *machinery*, a boiler supply pipe of sufficient elevation to enable the water to flow into the boiler notwithstanding the pressure of the steam. Stand-pipes are also used on the eduction pipes of steam pumps to absorb the concussions arising from pulsations and irregularities, caused by the unavoidable employment of bends and change in the direction of pipes. (2) In *hydraulic engineering*, a stand-pipe is a curved vertical pipe, arranged as a part of the main in waterworks to give the necessary head to supply elevated points in the district, or to equalize the force against which the engine has to act.

STANDARD. See ENSIGN; FLAG.

STANDARD, Battle of the, in English and Scottish history, a battle in which David I of Scotland, who had espoused the cause of Maud against Stephen, was signally defeated by the English under the Bishop of Durham. It was fought in the neighborhood of Northallerton, in Yorkshire, on 22 Aug. 1138, and it got its name from the fact that the English forces were gathered round a tall cross mounted on a car, and surrounded by the banners of Saint Cuthbert, Saint Wilfred and Saint John of Beverley. A peace was concluded between the two countries in the following year, David acknowledging the claims of Stephen to the throne of England.

STANDARD OIL COMPANY, The. Two very thrifty young men, John D. Rockefeller and an Englishman named M. B. Clark, after making small savings from their meagre

salaries for years and with close financing, determined to pool their little capital. They started a produce commission business in Cleveland, Ohio, in 1858, and were quickly doing a very large turn-over. In 1862 they gave a financial backing of \$4,000 to Samuel Andrews to enter into the mineral oil refining business. Andrews by his clever discoveries in refinery improvements soon made the concern wealthy and by 1865 it became the city's "most promising industry." Rockefeller sold out his interest in the commission business and devoted his time and money to the oil firm of Rockefeller and Andrews. A second refinery was soon started—William A. Rockefeller and Company, with John D.'s brother as partner. H. M. Flagler bought a partnership and was assigned selling quarters in New York City. John D. Rockefeller remained head of all the concerns. Five years after the start in the refining business each of the companies (1870) became combined in the title Standard Oil Company, with a capital of \$1,000,000. The partners were John D. Rockefeller, Henry M. Flagler, Samuel Andrews, Stephen V. Harkness and William Rockefeller. The numerous oil refineries were progressing at a marvelous rate, but in three or four years the Standard's progress was so greatly in advance of its rivals that they started an investigation to discover by what means this firm could be getting so far ahead of the others. The Standard Oil Company was found to be receiving rebates from the railroads which were not extended to its 25 rivals in Cleveland. While Cleveland was the largest refining centre in the United States and rapidly gaining in momentum, the Rockefeller interests, by 1870, were the largest operators in that field. The "wise" ones of that thriving city declared that the unflagging energy and commercial talents of the Standard partners assured the concern rapid progress; and the continuance of the extra substantial rebate in transportation cost, in spite of the clamors of its rivals, made their position positively dangerous to competitors. Cleveland still outstripped her rivals in the refining field, but the "Oil Regions" threatened to become a refining centre. Pittsburgh and the Pennsylvania Railroad were making the Cleveland future uncertain. The Standard had to face such facts as that the Pennsylvania Railroad and the Erie Railroad were allying themselves with the Empire Transportation Company and their rivals were putting up a refining plant in Jersey City connected with their pipe line supply. Railroad competition was becoming so keen rebates were given profusely and so much secret dealing was being revealed that each concern suspected its neighbor. The New York Central was forced into the scrimmage in self-protection, and now by 1871 the refining capacity was too great and supply was beyond demand, as so many were rushing into a field that had proven so prosperous. Refined oil prices began to drop. Rockefeller prices of 58¾ cents per gallon in 1865 had fallen to 26¾ cents by 1870—his 43 cent margin was wiped out except 17½ cents. Added to these ominous conditions foreign sales of refined oil were decreasing rapidly, for Europeans were beginning to import the crude oil and do their own refining. A scheme was set on foot (John D. Rockefeller and H. M. Flagler on oath

declared they were not the originators but disbelieved in the plan at first) among the Pennsylvania refiners to combine enough plants and shippers to awe the railroads into giving the combination special rebates "and drawbacks on that of other people." They felt assured thus the refiners could control the situation and regulate the amount refined and put up prices. The extra rebate had been allowed by the railroads to the Standard Oil Company as shippers of larger quantities than those of competitors. This concern now purchased, secretly, a charter of a company that was in liquidation and which permitted its owners the widest scope of commercial action. It was entitled "Southern Improvement Company" and was owned and organized by a combination of railroad men and oil refiners in 1872. They are said to have obtained control of one-tenth of the refining capacity of the country. Favorable freight contracts were made between the Southern Improvement Company and the Pennsylvania, Erie and New York Central railroads. Nearly all the Cleveland refiners subscribed later and one-fifth of the United States refining capacity was absorbed. In 1874 the Standard Oil Company acquired control of several leading refineries in Pittsburgh and Philadelphia as well as the great plant of Charles Pratt and Company at New York. From 1875 to 1879 the refiners were brought under the control or into the possession of the Standard Oil Company in ever-increasing numbers. All the oil region was gained by the combine and large numbers of works were dismantled and closed. By 1879 the Standard Oil Company held almost a monopoly in oil transportation facilities, including pipe lines, and the Standard "alliance" produced 95 per cent of the country's refined oil; this "alliance" consisting of the principal refining companies from Cleveland to Baltimore. In 1882 the Standard Oil Trust was formed for "convenience of control and management." It placed all the stock in the hands of trustees and corporations were organized in the different States that had business centres of the trust. The growth of the gigantic concern was steady and its prosperity was uninterrupted. In 1882 the properties under control of the Trust were valued at \$75,000,000; by 1892 this valuation had grown to \$121,631,312, 50 per cent of the increase being from profits invested. Dividends rose from 5¼ per cent in 1882 to 12 per cent in 1891. But 1892 opened up litigation and a suit to oust the corporation from its corporate rights for "abuse of corporate powers." The court decided the partnership of corporations illegal and that such a combine was in restraint of trade, illegal, etc. Hence the Standard Oil Company was dissolved into its 20 constituent companies. In 1899 the Standard Oil Company of New Jersey was organized to bring about closer unity and provision for the claims of small holders of trust certificates. The former Standard Oil Company of New Jersey had a capital of \$1,000,000, whereas the newer concern had an increased capital of \$110,000,000 with power to purchase and own stock of the different corporations, and since 1900 over \$97,000,000 of this capital stock had been utilized in purchasing other standard companies at par, the market value based on good will and earnings have been valued at \$650,000,000. Suit under the

Sherman Anti-Trust Law was instituted in 1906 in the United States Circuit Court at Saint Louis and its dissolution was ordered by the court, the decision being, on appeal, confirmed by the Supreme Court in 1911. But the distribution pro rata of the stock among subscribers left the strength of the companies a combined power equal to the prior condition. The figures of the earning capacity of the concern appear to range from \$8,000,000 from 1882, \$15,000,000 from 1886, by 1896 rising to \$34,000,000, and in 1905 amounting to \$57,459,356. Computation of the income of the entire congeries of companies owned by the Standard is not obtainable. Immense oil well and refining interests are held in the Baku district of Russia, in Mexico, in fact in every section of the world where mineral oil has been discovered in commercial quantities. The great lines of tank steamers crossing the seas to all parts of the globe and owned by the Standard Oil Company have a stupendous value in their entirety.

Y., 1910); Lloyd, H. D., 'Story of a Monopoly' (extract from *Atlantic Monthly*, New York 1881); Montague, G. H., 'The Rise and Progress of the Standard Oil Company' (New York 1904); Tarbell, I. M., 'The History of the Standard Oil Company' (New York 1904).

STANDARD TIME. See TIME.

STANDARD UNIT OF VALUE. See FINANCIAL PROBLEMS OF THE WORLD WAR.

STANDARDS, Bureau of, a subdivision of the Department of Commerce of the United States, authorized to deal with standards of measurement, standard values of constants, standards of quality, standards of mechanical performance and standards of practice. Its testing laboratories are located at Washington, D. C. The bureau occupies somewhat the same position with respect to the manufacturing interests of the country that the bureaus of the Department of Agriculture do to the agricultural interests. Its work calls for continuous scientific and technical investigations of the highest grade. It compares with its own standards of measurement the standards or measuring instruments of States, cities, scientific laboratories, educational institutions, manufacturers, government bureaus or the public, for which a nominal fee is charged, except in the case of the National and State institutions. The bureau gives advice concerning these standards or their use, whether it be in connection with the enactment of laws, regulations or ordinances concerning the weights and measures of everyday trade or in connection with precision standards used in scientific work and the industries. It gives advice upon request to State and city officials, public service commissions and public utility corporations regarding the standards of measurement, of quality or performance involved in legislation or regulation pertaining to public utilities. It also gives information to manufacturers in regard to standards of measurement, how to use them, how to measure the properties of materials or as to the fundamental physical and chemical principles involved; also, how to initi-

ate and carry out scientific investigations and tests on their own account in their particular fields of work. The staff of the bureau is organized according to the nature of the expert service involved. For example, the division of weights and measures deals with all matters pertaining to standards of length, mass, time, density and similar questions; the division of heat and thermometry deals with heat standards, the testing of heat-measuring apparatus, the determination of heat constants and all investigations where heat measurement is the essential and predominating factor. The electrical division is concerned similarly with the various electrical standards of measurement, the electrical properties of materials or the performance of electrical equipment. Similarly the work of the optical and chemistry divisions deals with the standards and questions arising in connection with these subjects. The structural engineering and miscellaneous materials division deals with the investigation, testing and preparation of specifications for these materials, such as the metals and their alloys, stone, cement, concrete, lime, clay, clay products, paints, oils, paper textiles, rubber and other miscellaneous materials. Its work has greatly expanded and now ranges from the measurement of the radiation of stars to a study of the efficiency and capacity of a vacuum cleaner. After the outbreak of the European War in 1914 the most interesting work of the bureau was that of helping manufacturers to produce at home and out of American materials products for which before they had been dependent upon foreign supplies. Its most notable successes in this field were in the paper and porcelain industries.

In 1915 the total appropriation for this bureau amounted to \$695,811.33. Consult *Annual Report of the Director, Bureau of Standards* (Washington), and publications upon definite subjects issued by the bureau from time to time.

STANDARDS OF LENGTH, MASS AND TIME. Standards of length, mass and time are the fundamental units used alike in the business of daily affairs and in the measurements and calculations of physical science.

The most important standards of length now used are the British yard and the international prototype metres. Both of these are legal standards in the United States, the metric system having been legalized in 1866. The relations of the yard and metre are shown by the following equations:

$$\begin{aligned} 1 \text{ yard} &= 0.9143992 \text{ metres.} \\ 1 \text{ metre} &= 1.093614 \text{ yards.} \\ 1 \text{ metre} &= 3.280843 \text{ feet.} \\ 1 \text{ metre} &= 39.37011 \text{ inches.} \end{aligned}$$

The most important standards of mass now used are the British pound and the international prototype kilograms. Both are legal standards in the United States. The relations of the pound and kilogram are shown by the following equations:

$$\begin{aligned} 1 \text{ pound} &= 0.453592428 \text{ kilograms.} \\ 1 \text{ kilogram} &= 2.20462234 \text{ pounds.} \end{aligned}$$

The above relations of the yard and metre and the pound and kilogram are the precise values determined by the International Bureau

of Weights and Measures. The relations which have been legalized, in the United States are:

1 metre = 39.37 inches.
1 kilogram = 2.2046 pounds.

The unit of time adopted by common consent, but used more especially in physical science, is the mean solar second, or 1/86400th part of the mean solar day. The minute, the hour, the day, etc., also in common use, are multiples of the mean solar second. The latter is derived, however, from the time of rotation of the earth, or from the interval between two successive transits of a fixed star across any meridian plane. This interval is called the sidereal day and it is equal in length to 86,164.1 mean solar seconds. The United States Bureau of Standards maintains fireproof vaults where platinum-iridium meter bars and kilogram weights are stored. This bureau makes tests of material for the use of the government, and conducts work looking to the maintenance of standards in all important industries. It has laboratories at Washington and Pittsburgh, and at the latter is the largest testing machine in the world. Consult 'Annual Reports, Bureau of Standards' (Washington, D. C.). See WEIGHTS AND MEASURES.

STANDING STONES. See STONES, STANDING.

STANDISH, Myles, English colonist in America: b. Lancashire, about 1584; d. Duxbury, New England, 3 Oct. 1656. Prior to 1603 he had gained a lieutenancy in the English force then serving in the Netherlands, but after the truce of 1609 joined the Pilgrim or Separatist colony at Leyden, though he never belonged to that communion, and sailed in the *Speedwell* and *Mayflower*. By reason of his experience in martial affairs, Standish was made military adviser to the colonists, and upon their arrival in America he headed exploring and scouting parties. In February 1621 he was chosen unanimously military captain of the colony. His force was always small, though recruited 11 November, and of the numbers and method of warfare of the Indians he knew nothing. But his demonstrations of power soon resulted in some degree of alliance with the powerful tribes along the coasts of Massachusetts Bay. In 1622 Thomas Weston established at Wessagusset (the present Weymouth) an independent settlement which quickly was involved in difficulties with the Indians. A great conspiracy of the savages was thereupon formed, the design being to destroy Plymouth after Weston had been similarly treated. Standish, with a file of eight, marched to Wessagusset, killed the hostile chiefs Pecksuot and Witawamat, defeated the Indians in battle and thus greatly increased the prestige of the struggling colony. He went to London in 1625, to adjust disputes arising with certain merchants who had advanced money on the colony's enterprise, and who at last abandoned their claims on payment of £1,800. In 1628 he arrested Thomas Morton (q.v.), whom he wanted to have shot. The last actual conflict in which he took a part was that in 1635, when he unsuccessfully attempted to dispossess the French who had seized a trading-post established by the colonists on the Penobscot. Besides his military commission, he held also the

posts of assistant to the governor, and, from 1644 to 1649, of treasurer of the colony. He was active and soldierly, and by his ability contributed very greatly to decide the success of the settlement. Longfellow's 'Miles Standish' contains numerous anachronisms and inaccuracies. Lowell, also, wrote an 'Interview with Miles Standish.' In 1872 the corner-stone of a monument 110 feet high and surmounted by a bronze figure of Standish was laid at Duxbury. Consult Abbott, J. S. C., 'Miles Standish, Captain of the Pilgrims' (New York 1908); Bradford, William, 'History of Plimouth Plantation, 1606-1646,' edited by W. T. Davis (New York 1908); Morton's 'New England's Memorial' (ed. 1855); Jenks, Tudor, 'Captain Myles Standish' (New York 1905); Johnson, 'Exploits of Myles Standish' (1897).

STANFIELD, stān'fēld, William Clark-son, English painter: b. Sunderland, 3 Dec. 1793; d. 18 March 1867. He began life as a sailor; occupied his spare time in sketching; received an engagement to paint scenery for the Old Royalty Theatre, London; became scene painter at Drury Lane in 1826; was elected a member of the Society of British Artists, and abandoned scene-painting in 1830. Among his pictures may be mentioned 'Mount Saint Michael' (1831); 'The Battle of Trafalgar' (1836); 'The Body of Nelson towed into Gibraltar' (1853); 'The Abandoned' (1856).

STANFORD, stān'fōrd, Sir Charles Vil-liers, English composer: b. Dublin, 30 Sept. 1852. He was educated at Cambridge, and continued his musical studies at Leipzig and Berlin. In 1877 a festival overture in B flat by him was performed at the Gloucester Festival, and a symphony at the Crystal Palace. Since that date he has produced numerous compositions in different styles, several of which have achieved a considerable degree of popularity. His best-known work is probably his choral setting of Tennyson's ballad of 'The Revenge,' which was produced at the Leeds Festival in 1886. His operas include 'The Veiled Prophet of Khorassan' (1881); 'Savonarola' (1884); 'Shamus O'Brien' (1896) and 'Much Ado About Nothing' (1901). In oratorio he has produced 'The Three Holy Children' (1885), and 'Eden' (1891), both written for Birmingham Festivals. His symphonies are an 'Elegiac Symphony' (1882); an 'Irish Symphony' (1887); a 'Symphony in F' (1888); and 'L'Allegro ed il Penseroso' (1895). The most important of his other works may be thus enumerated: a setting of Whitman's elegiac ode on the death of Lincoln (1884); settings of the three cavalier songs by Browning (1884); music for Æschylus' 'Eumenides' (1885) and Sophocles' 'Edipus Rex' (1887); settings of some psalms; a violin suite (1888); 'The Battle of the Baltic' (1891), a ballad for chorus and orchestra; string quartets; pianoforte sonatas; an ode on the opening of the Chicago Exhibition, the words being by Swinburne; masses, and Irish fantasies for the violin (1894). On the foundation of the Royal College of Music, in 1883, Dr. Stanford was appointed professor of composition and orchestral playing, and in 1887 professor of music at Cambridge. He was knighted in 1902.

STANFORD, Jane Lathrop, American philanthropist; b. Albany, N. Y., 25 Aug. 1825; d. Honolulu, Hawaiian Islands, 28 Feb. 1935. She was married to Leland Stanford (q.v.) and after his death in 1893 was occupied chiefly in fostering the development and extension of Leland Stanford Jr. University, which she had aided her husband to establish in memory of their son. In 1901 she increased her gifts to the university by further gifts of securities valued at \$13,000,000; her residence in San Francisco, valued at \$400,000, for a museum and art gallery; and 1,000,000 acres of land valued at \$12,000,000. She subsequently added other benefactions, thus making the university the wealthiest educational institution in the world. Mrs. Stanford established the children's hospital at Albany, N. Y., at a cost of \$130,000, and provided an additional \$100,000 to secure its maintenance; she also gave over \$160,000 to various schools and kindergartens. See **LELAND STANFORD JR. UNIVERSITY**.

STANFORD, Leland, American capitalist and philanthropist; b. Watervliet, Albany County, N. Y., 9 March 1824; d. Palo Alto, Cal., 21 June 1893. He studied law and commenced its practice at Port Washington, Wis., but in 1852 went to California and engaged in mining for four years. In 1856 he founded a business in San Francisco which became the nucleus for a fortune estimated at over \$50,000,000. In 1860 he entered public life as a delegate to the convention that nominated Abraham Lincoln for the Presidency. About this time he became president of the Central Pacific Railroad, an enterprise in which he was deeply interested financially. He was governor of California, 1861-63; and United States senator, 1885-91. He did much to promote the agricultural development of California and to increase its transportation facilities, but he will probably be longest remembered, however, as the founder of Leland Stanford Jr. University, for which he made an initial gift of \$20,000,000. This work, begun in commemoration of his son, was continued by his wife, Jane Lathrop Stanford (q.v.), who erected at Palo Alto a beautiful and costly memorial church to his memory. See **LELAND STANFORD JR. UNIVERSITY**.

STANG, William, Roman Catholic bishop of Fall River, Mass.; b. Langenbruchen, Germany, 21 April 1854; d. Rochester, Minn., 2 Feb. 1907. Received his primary education in the German Gymnasia and his philosophical and theological training at the American College, Louvain. Ordained priest in Mechlin, 15 June 1878, and came to Providence, R. I., in October of the same year. Was successively assistant and rector of the Cathedral, pastor of Saint Ann's and Saint Edward's parishes, and superior of the Diocesan Missionary Band. He was consecrated first bishop of Fall River in the cathedral, Providence, 1 May 1904. Among his best known works are 'Life of Martin Luther'; 'The Eve of the Reformation'; 'More About the Huguenots'; 'Germany's Debt to Ireland'; 'Pastoral Theology'; 'Historiographia Ecclesiastica'; 'Theologia Fundamental Moralit'; 'Spiritual Pepper and Salt.'

STANHOPE, stān'ōp, an English family, to which three peerages belong: Chesterfield (barony of Stanhope from 1616, and earldom of Chesterfield from 1628); Stanhope (barony, 1717; earldom, 1718); and Harrington (barony, 1729; earldom, 1742). James, 1st Earl Stanhope; b. Paris, 1673; d. London, England, 5 Feb. 1721. He entered the army and served as brigadier-general at the capture of Barcelona in 1705. In 1708 he was appointed commander-in-chief of the British forces in Spain, and in the same year he took Port Mahon, and thus made himself master of the Island of Minorca. After the accession of George I, he devoted himself to politics and became the favorite minister of that monarch, to whom he owed his titles of baron and earl. Charles, the 3d earl, grandson of the preceding; b. London, 3 Aug. 1753; d. Chevening, Kent, 15 Dec. 1816. He invented a printing press and built two calculating machines, and was a patron of science. He approved the French Revolution, openly avowing republican sentiments, and as a member of the House of Lords he favored parliamentary reform, the abolition of negro slavery, the freedom of the press, and the independence of juries. He was father of the celebrated Lady Hester Stanhope (q.v.). The 5th Earl Stanhope (1805-75), grandson of the last noticed, was author of a 'History of England from the Peace of Utrecht to the Peace of Versailles' (1713-83).

STANHOPE, Lady Hester Lucy, eccentric English woman, daughter of the 3d Earl Stanhope (q.v.); b. Chevening, Kent, 12 March 1776; d. near Sidon, Syria, 23 June 1839. Her own home was uncongenial and in 1803 she went to reside over that of her uncle, William Pitt, becoming his most trusted confidant. After his death in 1806 she received a pension, but her life being much embittered by her loss of power through his death, and saddened also by the death of her favorite brother and a lover, she left England in 1810, and after traveling over various parts of the East, settled in Syria, where she resided for the rest of her life, living latterly about eight miles from Sidon, at a villa of her own construction, called D'Joun, which was situated on a solitary mountain, remote from any village. The rich presents which she made to the Turkish pashas gave her a great influence over them for a time, though it was afterward greatly diminished. She habitually wore the costume of a Mohammedan chief, and adopted many features of their religion, discovering many similarities in the Koran and the Bible. The Bedouins, or wild Arabs, whom her wisdom and kindness had won, looked up to her, not only as a benefactor, but as a being of a superior order. She is 'the crazy Queen of Lebanon' to whom Whittier alludes in 'Snow-bound.' Her guests also included Lamartine (1832) and Kinglake (1835). Consult Kinglake, 'Eothen'; Meryon, 'Memoirs of Lady Hester Stanhope' (1846); Hamel, 'Lady Hester Lucy Stanhope' (New York 1913).

STANISLAUS, stān'is-lās, or **STANISLAS I**, Leszcynski, lēs-chūn'skē, king of Poland; b. Lemberg, Galicia, 20 Oct. 1677; d. 23 Feb. 1766. In 1704, being then woywode of Posnania, and general of Great Poland, he was deputed by the assembly of the states at War-

saw to wait upon Charles XII of Sweden, who invaded the kingdom with the view of dethroning Augustus of Saxony. Charles immediately resolved to raise him to the throne of Poland, which he effected at an election held in July 1704. He was, however, soon after driven from Warsaw by his rival Augustus; but another change brought him back to that capital, where he was crowned, with his wife, in October 1705; and the next year Augustus was compelled formally to abdicate. The fatal defeat of his patron, Charles XII, at Pultava, in 1709, again obliged him to retreat into Sweden, where he endeavored to join Charles at Bender, in disguise; but, being detected, he was held captive in that town until 1714. He remained in obscurity until 1725, when his daughter, the Princess Mary, was selected as a wife by Louis XIV, king of France. On the death of Augustus, in 1733, an attempt was made by the French court to replace Stanislaus on the throne of Poland; but, although a party supported him and proclaimed him king, his competitor, the electoral Prince of Saxony, being aided by the emperors of Germany and Russia he was obliged to retire. He endured this, like every other reverse of fortune, with great resignation, and at the peace of 1736, formally abdicated his claim to the kingdom of Poland, on condition of retaining the title of king, and being put in possession for life of the duchies of Lorraine and Bar. Thence forward he lived as the sovereign of a small country, and acquired the appellation of "Stanislaus the Beneficent." He not only relieved his people from excessive imposts, but, by strict economy, was able to found many useful charitable establishments, and to patronize the arts and sciences. He wrote some treatises on philosophy, morals and politics, which were published under the title of *Œuvres du Philosophe bienfaisant* (8vo. 1765). Consult Des Reaulx, *Le Roy Stanislas et Marie Leszcynski* (Paris 1895).

STANISLAUS, or STANISLAS II, Augustus, the last king of Poland, son of Count Stanislaus Poniatowski: b. Woczyn, Lithuania, 17 Jan. 1732; d. Saint Petersburg, 12 Feb. 1798. In 1752 he first appeared as a deputy in the Polish diet, where he soon attracted attention by his oratory. Augustus III sent him on a mission to the Empress Elizabeth at Saint Petersburg, and on this occasion he acquired the peculiar favor of the Princess (afterward Empress) Catharine. After the death of Augustus, the influence of Catharine secured the election of her favorite as his successor (Sept. 1764), and he was crowned at Warsaw on 25 Nov. 1764. Although of excellent ability and noble disposition, he was yet unable to do anything for the good of his country, because he lacked the strength of character necessary to check the license of the nobles, and to withdraw himself from Russian influence. In 1772, when the first partition of Poland was made, Stanislaus in vain protested against it, while his resistance to the second partition of Poland had only this consequence, that after the capture of Warsaw the Empress Catharine caused him to be brought to Grodno, where he was compelled to sign the treaty for the third partition of Poland, and on 25 Nov. 1795, also to sign his own abdication. After the death of Catharine, Paul I brought him to Saint

Petersburg, where he lived for the rest of his life on a pension allowed him by the emperor. Consult *Memoires secrets et inédits de Stanislas* (1862); Bain, *The Last King of Poland* (1909).

STANLEY, stān'li, Arthur Penrhyn, English Anglican clergyman and author, popularly known as Dean Stanley: b. Alderley, Cheshire, 13 Dec. 1815; d. London, 18 July 1881. He was educated first at Rugby, where he conceived an abiding love and veneration for Dr. Thomas Arnold (q.v.) and gained a unique position in the school. In 1834 he entered Balliol College, Oxford, where he had a brilliant career and in 1838 was elected a Fellow of University College. He took deacon's orders in 1839 and priest's in 1843, became a college tutor in 1843 and was appointed in 1845 preacher to Oxford University. In that capacity he preached four sermons, which were published as *Sermons on the Apostolic Age*, in 1847, at a critical time in the religious history of Oxford. In these Stanley stood aloof from both the Evangelicals and the high churchmen, taking, rather, a rationalistic position. He was presented to a canonry of Canterbury in 1851 and shortly afterward traveled extensively in Palestine and Egypt. In 1856 he was appointed professor of ecclesiastical history at Oxford and canon of Christ Church, and in 1863 was made dean of Westminster. In this position, as the acknowledged head of the Broad Church party, he exercised an important influence, though the width of his sympathy and his tolerant spirit exposed him to attacks from many of narrower views within the Anglican Church. In 1863 he married Lady Augusta Bruce, daughter of the 7th Earl of Elgin (died 1876), to whom he owed much of his social popularity. He visited America in 1878 and delivered many notable sermons and addresses (see bibliography). He was the author of numerous works, among which are *Life of Arnold* (1844); *Memoir of Bishop Stanley*, his father (1850); *Memorials of Canterbury Cathedral* (1854); *Commentary on the Epistles to the Corinthians* (1855); *Sinai and Palestine* (1856); *Three Introductory Lectures to the Study of Ecclesiastical History* (1857); *Lectures on the History of the Eastern Church* (1861); *Lectures on the History of the Jewish Church* (1863-76); *Sermons in the East* (1863); *Memorials of Westminster Abbey* (1868); *Essays on Questions of Church and State* (1870); *The Athanasian Creed* (1871); *Lectures on the History of the Church of Scotland* (1872); *Addresses and Sermons delivered at St. Andrews* (1877); *Addresses and Sermons delivered in the United States and Canada* (1879); *Christian Institutions* (1881). The breadth and tolerance characteristic of Stanley's religious views were well shown in his attitude toward Bishop Colenso, whom he supported without endorsing his opinions on the Pentateuch and in his article on the famous *Essays and Reviews* contributed to the *Edinburgh Review* of April 1861. Consult Bradley, *Recollections of Arthur Penrhyn Stanley* (1883); Prothero, *Life and Correspondence of Dean Stanley* (1893) and *Letters and Verses of Dean Stanley* (1895).

STANLEY, David Sloane, American soldier: b. Chester, Ohio, 1 June 1828; d. 1902. He was graduated from West Point Military

Academy 1852. As an officer in the Federal army he took an active part in the Civil War, commanding a division at Iuka and serving in the battles of the Atlanta campaign. He was promoted brigadier-general, United States army, in 1884, later was brevetted major-general and was retired 1892.

STANLEY, Sir Henry Morton, Anglo-American explorer: b. near Denbigh, Wales, 28 Jan. 1841; d. London, 10 May 1904. His name was originally John Rowlands and at three he was placed in the poorhouse at Saint Asaph, where he remained for 10 years, making such progress that when he left the institution he was engaged as an instructor for other children at Mold, Flintshire. In 1857 he sailed as cabin-boy on a vessel bound for New Orleans, where he was adopted by a merchant who gave him his name, but who died without making a will, thus leaving his adopted son penniless. At the outbreak of the Civil War Stanley entered the Confederate army but was shortly afterward taken prisoner and when discharged volunteered in the United States navy and later became acting ensign on the ironclad *Ticonderoga*. At the close of the war he went to Turkey and Asia Minor as a newspaper correspondent and in 1867-68 was engaged as special correspondent for the *New York Herald* on the Abyssinian expedition, winning a reputation as a journalist by sending his account of Lord Napier's victory to London in advance of the official despatches. He represented the same paper in Spain during the Carlist War in 1868 and in 1869 accepted the mission from the proprietor of his paper "to go and find Livingstone," from whom no tidings had come for more than two years. He was given full control of the expedition and after attending the opening of the Suez Canal, visiting Constantinople, the Crimea, Palestine, the valley of the Euphrates, Persia and India, he set sail from Bombay, for Africa, 12 Oct. 1870. He reached Zanzibar on the eastern coast of Africa in January 1871, organized an expedition of 192 men, divided them into five parties and set out on 21 March. He found Livingstone at Ujiji on Lake Tanganyika, 10 Nov. 1871 and remained with him four months, after which, the veteran explorer refusing to abandon his enterprise until it was completed, Stanley furnished him with supplies and returned to England. In 1874 Stanley set out on a second African expedition under the auspices of the *New York Herald* and the *London Daily Telegraph*. Reaching Zanzibar in the autumn of that year, he learned of Livingstone's death and resolved to shape his course to the northwest. He explored the equatorial lake region, circumnavigated for the first time Victoria Nyanza, proving it to be the largest-fresh-water lake in the world instead of a series of lagoons, discovered the Shimeeyu River and afterward, continuing to the westward, discovered that Albert Nyanza was not connected with Lake Tanganyika as had been supposed. He returned to England in 1878 having on his return journey traced the Kongo River from its source to its mouth. In 1879 he again set out for Africa on the Belgian enterprise, which resulted in the development of the Kongo Free State. He visited the United States in 1886 on a lecturing tour and in 1887

organized the relief expedition in search of Emin Pasha whom he met on the Albert Nyanza 28 April 1888 and escorted him to the east coast discovering the Ruwenzori Mountains south of Albert Nyanza on the return trip. He reached England in 1890, visited the United States and Australia, on lecturing tours in the following year and in 1895-1900 sat in Parliament for North Lambeth. He was knighted in 1899. His publications include 'How I Found Livingstone' (1872); 'Through the Dark Continent' (1878); 'The Congo, and the Founding of its Free State' (1885); 'In Darkest Africa' (1890); 'My Dark Companions and Their Strange Stories'; 'Slavery and the Slave Trade in Africa' (1893); 'Through South Africa' (1898), etc. Consult his 'Autobiography,' edited by his wife (London 1909); Wauters, A. J., 'Stanley's Emin Pasha Expedition' (London 1890).

STANLEY, Thomas, English scholar: b. Comberlow, Hertfordshire, 1625; d. London, 12 April 1678. He was graduated at Cambridge in 1641, but held also a master's degree at Oxford. He entered the Middle Temple and practised law all his life, but is best known as a scholar. His works include translations from the Greek, Latin, French, Spanish and Italian poets; the 'History of Philosophy' (1655-62), dealing with the Greek philosophers, and an edition of Æschylus (1663-64), with Latin translation and commentary. These two works long remained standards, the latter being translated into several languages.

STANLEY FALLS, Kongo Free State, a cataract and an important trading station on the Kongo River about 1,400 miles from its mouth; also an administrative district of the Kongo State.

STANLEY POOL, Kongo Free State, a lake-like expansion of the Kongo River, 325 miles from its mouth and about 80 square miles in area. It was discovered in 1877 by Stanley, who founded here the station of Leopoldville, which became the principal base for trade and exploration in the Kongo Basin. Stanley Pool is also the name of an administrative district of the Kongo State.

STANNARD, stăn'ard, Henrietta Eliza Vaughan Palmer ("JOHN STRANGE WINTER," "VIOLET WHYTE"), English novelist: b. York, England, 13 Jan. 1856; d. 1911. She was married to Arthur Stannard in 1884. She was a prolific writer after her first appearance in print in 1874, her novels numbering above 70. She was the first president of the Writers' Club in 1892. Among her works, chiefly tales of army life, are 'Cavalry Life' (1881); 'Bootles's Baby' (1885); 'A Siege Baby' (1887); 'Heart and Sword'; 'A Blaze of Glory'; 'Uncle Charles'; 'Cherry's Child,' etc.

STANNARIES, mines from which tin-bearing ore is dug. The most noted stannaries are those of Devon and Cornwall in England. Around the mines of these two counties there has arisen a body of law and customary usage peculiar to the locality and not imitated or duplicated in any other mines in England. By early usage the prerogative of the Crown was extended so as to cover these tin mines, although elsewhere it reaches only to gold and silver. King John in a charter to the tinners gave them the privilege of mining and working

anywhere in the two counties and this was confirmed by subsequent monarchs, until Edward III created his son Duke of Cornwall with the stannaries as a perpetuity of the duchy. The Duke who is now always the Prince of Wales is represented by a warden and vice-wardens. In former times representative assemblies of the tanners (called parliaments) were summoned by the warden for the regulation of the stannaries and redress of grievances: the last of them was held in 1752. The Stannary Courts are courts of record held by the warden and vice-warden (of the same limited and exclusive character as the courts-palatine), in which the tanners have the privilege of suing and being sued. They were remodeled and regulated by a series of acts of Parliament. Appeals from them are now taken to the Court of Appeals, and finally to the House of Lords.

STANNITE, or **TIN PYRITES**, a brittle gray or black tin ore, popularly called "bell metal ore" by the miners of Cornwall, England, its chief locality. It is identical with tin pyrites, and was only known massive until recently discovered in small tetrahedral crystals in Bolivia. Its hardness is 4; specific gravity 4.3 to 4.5; streak blackish; color steel-gray to iron-black. It is a sulphide of tin, copper, iron and some zinc.

STANOVOI (stā-nō-voi') **MOUNTAINS**, Siberia, a mountain range traversing eastern Siberia from the northern boundary of Mongolia to the Bering Strait. Its general course is northeast, but after traversing the Transbaikal district and running along the northern boundary of the Amur district, it skirts the shores of the Sea of Okhotsk in a large zigzag. It terminates in East Cape on the Bering Strait. Its total length is about 2,600 miles. The southwestern portion, which is known as the Yablonoi Mountains, is less regular than the northern branch and spreads out into numerous parallel chains and transverse spurs. This part is heavily forested, while the forests disappear north of the 60th parallel. The Stanovoi range proper is a steep mountain-wall with rugged peaks reaching a height of over 8,000 feet. The whole range forms the divide between the Arctic and Pacific oceans, and feeds the Yenisei, Lena, Indigirka, Kolyma and Amur rivers.

STANOYEVICH, **Milivoy Stoyan**, Serbian essayist and author: b. Koprivnica, Kraina, Serbia, 14 Feb. 1882. He studied at Belgrade University, where he successfully competed for academic prizes in literary essays. He graduated from that institution in 1907, and was immediately appointed professor *ad interim* of modern languages at Zaječar College. He came to the United States in 1908 and continued his pursuits in literature, sociology and economics at Columbia University and the University of California, receiving from the last-named institution his degree of M.L. (1914). In 1915 he became a lecturer on Slavonic literature at the University of California, and in 1916 he was nominated as political adviser on Slavic affairs in the office of the Russian consul-general at San Francisco. He has been editor of several Yugoslav publications and frequent contributor to the American periodicals, besides having written 'Omladina, u

Sadašnjosti' (1907); 'Figure u Pesmama' (1907); 'Prevodi u Srpskin Zabavnicima' (1908); 'Veština Pisanja' (1915); 'Pessimisme et Optimisme dans la Sociologie' (in joint collaboration with his brother, Milosh S.) in 1913; 'Tolstoy's Theory of Social Reform' (1914); 'Russian Foreign Policy in the East' (1916), etc. His writings are marked by a fresh and vigorous style, by refined simplicity and incisive diction. His studies are full of delicate observations of human nature and he may be justly regarded as a representative writer of Serbian prose.

STANTON, **Edwin McMasters**, American statesman and jurist: b. Steubenville, Ohio, 19 Dec. 1814; d. Washington, D. C., 24 Dec. 1869. His paternal ancestors were Quakers originally from Massachusetts but later settled in North Carolina, and his mother was a Virginian. At the age of 13 upon his father's death he began to work, and at 17 entered Kenyon College but was obliged to leave after two years for lack of means. After three years of study he was admitted to the bar in 1836 and married.

He joined the Democratic party on the issue of nullification, and in 1837 was elected prosecuting officer of his county. After serving for two years he returned to private practice, and in 1847 he moved to Pittsburgh where he soon took rank among the leaders of the Pennsylvania bar. In 1856 he changed his residence to Washington, and in 1858 was sent to California as special counsel of the United States in the cases growing out of land grants made by the Mexican government before the treaty of 1848. He added greatly to his reputation by his conduct of this litigation. During these years he took no part in politics but sympathized with the Free-soil wing of the Democratic party and favored the Wilmot Proviso. In 1856 he supported Buchanan, and in 1860 voted for Breckinridge, believing that the election of Lincoln would imperil the Union.

When Buchanan's Cabinet divided in December 1860 and Cass, the Secretary of State, resigned, Attorney-General Black took his place and Stanton was made Attorney-General 20 Dec. 1860, the day when the ordinance of secession was adopted in South Carolina. At his first Cabinet meeting the question was presented whether Major Anderson should be ordered back to Fort Moultrie. Floyd, the Secretary of War, and his southern associates insisted that this should be done, while Stanton with Black and Holt vigorously opposed them, threatening to resign if such orders were issued. Their attitude drove the secessionists from the Cabinet and redeemed the close of Buchanan's administration. During the remainder of the administration he was active in studying the plans of the secessionists and considering how to defeat them and protect Washington. He feared insurrection or assassination to prevent Lincoln's inauguration, and his influence helped to persuade President Buchanan that regular troops should be ordered to Washington.

The attack on Fort Sumter found him a strong supporter of the national authority and outspoken in calling upon all loyal men to stand by the government. On 13 Jan. 1862, Mr. Lincoln appointed him Secretary of War in place of Simon Cameron. Stanton had criticized Lin-

coln severely and had not even met him since his inauguration, but Lincoln selected him for his ability and because he was a representative of the Democratic Unionists, whose support was essential. The wisdom of the choice was signally vindicated. The whole system of the War office was inefficient and reorganization was imperatively demanded. Stanton brought to his work great executive ability, prompt decision and a strong will which made itself felt through the whole military service. He had scant patience with men who were seeking personal advantages, or with frivolous calls upon his attention. Hence his manner was brusque, impatient and decided, and he made many enemies.

He advised the passage of a law authorizing the President to take possession of all the railroad and telegraph lines of the United States, and this was at once enacted. He ordered that all contracts for supplies and munitions be in writing, appointed a commission to investigate and determine what valid contracts were outstanding, and waged vigorous war upon fraudulent contractors. By an order of 14 February he directed the release of all persons who had been arrested on suspicion of disloyal practices, with certain exceptions, upon their giving their parole not to aid the rebellion. From that time such arrests were made only under military authority, which was exercised on the theory that all doubts were to be resolved in favor of the country. No part of Stanton's career shows more loyalty to his country than his patience with McClellan during the first six months of 1862, but the latter's delay in moving his army to the support of Pope, his disregard of orders, and his whole conduct during the critical weeks which preceded Lee's invasion of Maryland at length satisfied Stanton that he should be removed, and in the last days of August he tried to unite the Cabinet in recommending this step, but Mr. Lincoln felt that McClellan's popularity and the political situation made it necessary to give him the command of the army. Stanton disapproved this action as did Mr. Chase, but the President took the responsibility. McClellan's conduct of the Antietam campaign, his inexcusable delays and almost direct insubordination increased Stanton's feeling and at length convinced the President, and McClellan was dismissed from active service.

Taking office as a Democrat, Stanton early felt the importance of emancipation as a war measure, and when on 22 July 1862, Mr. Lincoln laid before the Cabinet a proclamation declaring that all slaves in the seceded States should be free on a fixed day, Stanton and Bates, the Attorney-General, were in favor of issuing it at once, while Seward and Chase opposed it. Stanton approved the issue of the proclamation after Antietam, and in his annual report made a powerful argument in support of the measure. When in the next year after the defeats of Fredericksburg and Chancellorsville, Lee a second time crossed the Potomac, Hooker was relieved and Meade appointed to the command by Stanton's advice, and during the critical summer and autumn of 1863 he met every emergency successfully.

When it was apparent that General Rosecrans was not in a condition to retain the com-

mand, Stanton summoned Grant from New Orleans to Louisville, himself met him there and after a full conference placed him in command of the Western armies, giving Thomas command at Chattanooga. The immediate success of General Grant in his new command with the crushing defeat of Bragg's army made the whole military situation much clearer, and General Grant's appointment to the command of the army and his removal to Virginia followed as a matter of course. After Appomattox, General Sherman agreed upon terms with General Johnston, which provided not only for the surrender of the latter's army but for the settlement of vital political questions, and the agreement was disapproved by the Administration. Stanton stated the reason in a dispatch to General Dix that the public might understand why General Sherman was overruled. His statement was clear and poignant and while it reflected on General Sherman's discretion in consenting to such an arrangement, the general himself was not criticized. Sherman held Stanton especially responsible for the action of the government and became very hostile to him.

Nothing in the history of the Civil War is more remarkable than the speed with which the vast armies of the United States were dissolved. On 1 May 1865, a million men were on the rolls of the army. In hardly more than 60 days nearly 700,000 of them were returned to their homes. The grand review of the two great armies held in Washington 22 and 23 May 1865 showed the military force of the United States at its greatest. In little more than a month most of that force was engaged in the labors of peace. Stanton had made this possible.

Stanton remained in the Cabinet of President Johnson, and in the struggle between the President and Congress over the policy of reconstruction, sympathized with Congress. He felt that the President's policy meant the return of the disloyal element to power in the Southern States and he could not contemplate such a result without indignation. The partisans of the President demanded his resignation, while the leading Republicans besought him to remain, feeling that his presence in the War Department was an insurance against violence. His position was extremely disagreeable, but he held it with persistent courage, taking no part in the discussion and making no public expression of his views. He simply remained at his post and discharged his duty. The Tenure of Office Act had been passed in part to prevent the removal of Stanton. He opposed its passage, advised the President to veto it and desired its defeat after the veto.

This act and the provision that the President should issue orders to the army only through the general of the army, effectually took the control of the army away from the President and he wished to regain it. When Congress adjourned in the summer of 1867 the President sounded General Grant as to removing Stanton from office. Grant counseled him against it. Thereupon the President asked for Stanton's resignation, which was refused and the refusal was applauded by the Republican leaders. A week later the President suspended him from office without stating any cause and directed him to turn over all public records and property to General Grant, whom he appointed Secretary *ad interim*. Stanton in reply denied

Elizabeth Cady Stanton

his right to suspend him without legal cause, but under protest obeyed the order. When Congress reassembled in December 1867 the Senate refused to concur in the suspension and Stanton was thus reinstated. The President was very much irritated and after an interval spent in endeavoring to persuade General Sherman to accept the position, removed Stanton on 21 Feb. 1868 and appointed Lorenzo Thomas Secretary of War *ad interim*. Stanton declined to obey this order, the Senate by resolution denied the President's power to remove him and the House voted to impeach the President. The trial of the President followed and ended on the 26th of May, and during its progress General Schofield had been nominated to the Cabinet as Secretary of War. When the Senate failed to convict the President, Stanton at once retired and the nomination of Schofield was confirmed.

He left the office which he had held for more than six years, a comparatively young man, but broken in health by the unremitting toil and anxiety which he had undergone. His income which had been considerable when he took office had been so reduced that he had nothing but his house in Washington, and he was obliged to resume the practice of his profession. He argued several important cases, but his powers were exhausted, and he gradually failed. His last argument was made at a hearing in his own library in December 1869, and he never left the house again. The approaching resignation of Judge Grier made a prospective vacancy on the Supreme Bench and on the recommendation of the leading men in both Houses of Congress, President Grant nominated Stanton to the place on 20 Dec. 1869. His nomination was at once confirmed and he lived to feel the pleasure of receiving the only office which he ever desired, but his work was done and he died four days later. A sincere, unselfish, patriotic man, the result of the Civil War was due in no small part to his labors. Consult Gorham, G. C., 'Life and Public Services of Edwin Y. Stanton' (2 vols., Boston 1899); De Witt, D. M., 'The Impeachment and Trial of Andrew Johnson' (New York 1903); Flower, F. A., 'Edwin McMasters Stanton' (Akron, Ohio 1905).

MOORFIELD STOREY,
Author 'Life of Charles Sumner.'

STANTON, Elizabeth Cady, American reformer: b. Johnstown, N. Y., 12 Nov. 1815; d. New York, 26 Oct. 1902. She was graduated from Emma Willard Seminary, Troy, N. Y., in 1832 and was married to Henry Brewster Stanton (q.v.) in 1840. Her attention was first attracted to the disabilities of her sex when at 15 she was prepared to enter college and found none in which she could obtain the education which her brothers received. She afterward studied Blackstone, Story and Kent, and while in London, in 1847, met Lucretia Mott, with whom in the following year she issued the first call for a woman-suffrage convention to be held in her home at Seneca Falls. From that time her career was one long struggle for equal rights for both sexes. The general principles for which she strove were equal educational advantages, equal rights of suffrage and of property, and more intelligent divorce laws. She addressed the New York legislature on the rights of mar-

ried women in 1854 and again in 1860, advocating divorce for drunkenness. In 1866, she offered herself as a congressional candidate and for 25 years annually addressed congressional committees in the endeavor to gain a constitutional amendment granting enlarged privileges to women. She was president of the Women's Loyal League in 1861 and of the National Woman Suffrage Association in 1865-93. She traveled and lectured in all parts of the United States and also made addresses in England, Scotland and France. Throughout her entire career, Mrs. Stanton's personal life was a model of the fulfillment of the duties of a wife and mother, her public career never operating to the neglect of her social and home life. While the changes which have been wrought cannot definitely be declared the result of the exertions of Mrs. Stanton and her immediate associates, a great change certainly came about in her lifetime. The education within the reach of her brothers but unattainable for herself in her girlhood is now within the reach of any determined girl, and the changes in legislation are even more noticeable. The laws which placed a woman's property absolutely at her husband's disposal have been replaced by those which give her equal rights with him, or possibly superior, since the law recognizes no claim on the woman for family support, and her earnings are her own. Her intellect, energy and perseverance, and her womanly traits made her generally respected, and she is rightfully regarded as the mother of the movement. She presided over the first International Council of Women held in Washington in 1888, was one of the founders and afterward editor of *The Revolution*, and a frequent contributor to English and American magazines. She published 'Eighty Years and More' (1895); and was joint author of 'The History of Woman Suffrage' (1881-86) and edited 'The Woman's Bible' (1895).

STANTON, Frank Lebby, American journalist and poet: b. Charleston, S. C., 1857. He has resided in Atlanta, Ga., since 1894 and is now on the editorial staff of the *Atlanta Constitution*. He has published 'Songs of the Soil'; 'Comes One With a Song' (1898); 'Songs from Dixie Land' (1900); and 'Up from Georgia' (1902); and 'Little Folks Down South.'

STANTON, Henry Brewster, American abolitionist: b. Griswold, Conn., 29 June 1805; d. New York, 14 Jan. 1887. He was prominent in the anti-slavery movements of 1837-41. In 1847 he was admitted to the bar and achieved a high reputation in patent law. In 1858-60 he assisted in the reorganization of the Republican party, and from 1868 was on the editorial staff of the *New York Sun*. He has published 'Sketches of Reform and Reformers in Great Britain and Ireland' (1849); 'Random Collections' (1886).

STANTON, Robert Brewster, American civil and mining engineer: b. Woodville, Miss., 5 Aug. 1846. He graduated at Miami University—A.B., 1871; A.M., 1878; (hon. A.M. University of Wooster, 1885); was resident engineer Cincinnati Southern Railroad, 1874-80; division engineer Union Pacific Railway, 1880-84. Since 1884 has been in private practice as consulting civil and mining engineer. Among

other engagements made survey as chief engineer through the Grand Cañon of the Colorado, 1889-90; special work on the British Columbia landslides for the Canadian Pacific Railway, 1896; examined and appraised the value of railroads in the States of Michigan, Kansas and Washington, 1906 and 1910; located railroad line from Chicago to Saint Louis, 1902, and from Butte, Mont. to Boise, Idaho, 1905. He engaged in mining operations and explorations at various times from 1884 to the present date, throughout the United States, Canada, Mexico, the West Indies and the Dutch East Indies; engineer and general manager, Flint Idaho Mining Company, 1886-88; and the Hocumac Mining Company, 1893-94; special work in copper and nickel mines in Canada, 1892 and 1903; explored and examined gold mines in the Island of Sumatra, 1904; examined and reported upon the Cananea, Mexico, copper mines, 1906; gold mines in California, 1893, 1903 and 1907, and in Utah and Arizona 1898-1901; manganese mines in Washington, 1910; gold mines in Nova Scotia, 1913 and on iron and manganese mines in Cuba, 1909-14. He is the author of 'Availability of the Cañons of the Colorado River for Railway Purposes' (1882); 'The Great Landslides of the Canadian Pacific Railway,' etc (1898), and monographs and lectures on the Grand Cañon.

STANWIX, stán'wíks, John, English soldier: b. 1690; d. Irish Channel, December 1766. He entered the army in 1706, was made lieutenant-colonel, 1745; and governor of Carlisle 1752. After General Braddock's defeat Stanwix was sent to America in command of a battalion of the Royal Americans, and in 1758 was made brigadier and sent up the Hudson to the Oneida portage where he built Fort Stanwix. In 1759, while Wolfe was storming Quebec, he was in command in Pennsylvania, rebuilt Fort Duquesne, was promoted to major-general, and returned to England in 1760. He was made lieutenant-general in 1761 and governor of the Isle of Wight in 1763.

STANWOOD, stán'wúd, Edward, American editor and author: b. Augusta, Me., 16 Sept. 1841. He was graduated at Bowdoin College in 1861 (Litt.D., 1894), was assistant editor of the *Boston Daily Advertiser*, 1867-82, and editor, 1882-83, and managing editor of the *Youth's Companion*, 1884-1913. He has published 'History of Presidential Elections' 1884; 'History of the Presidency' 1898; 'American Tariff Controversies in the Nineteenth Century' 1903; 'The Life of James G. Blaine' 1905; Volume 2 of 'History of the Presidency' 1912.

STANYUKOVITCH, Konstantin Mikhaïlovitch, Russian author: b. Sevastopol, 1844; d. 1903. He was the son of an admiral and entered the navy at 16, but resigned in 1864 and thereafter devoted himself to literary work at Saint Petersburg. His work, consisting of sea stories, social studies and humorous sketches, appeared in the leading Russian journals, later appearing in book form. Among his numerous works the more important are 'The Sincere People'; 'The Story of One Life'; 'The Indifferent People'; 'Priests'; 'Sea Tales.' His collected works were published (Saint Petersburg 12 vols., 1906-07).

STANZA, a group of four or more lines so connected with each other by metre and

rhyme as to form one of the regular divisions of a poem. The use of the word stanza for a two-line verse is not to be commended. Two rhymed lines form a couplet, three a triplet. Stanzas are usually from four to 16 lines in length, and the lines mostly rhyme alternately or in couplets, though other arrangements are frequent. In Byron's 'Don Juan,' the eight lines are rhymed thus: 1 2 1 2 1 2 3 3, the same figures indicating rhymes. This particular form of stanza is called the *ottava rima*.

STAPELIA, a genus of cactus-like plants of the family *Asclepiadaceae*, about 80 species of which are natives of South Africa. They have angular, generally four-sided, leaflets, green stems and branches, covered with excrescences; bear large, showy, grotesquely mottled or barred flowers irregularly in angles and notches of the stems. Because of their fetid odor they are popularly known as carrion-flowers, a name shared by several other unrelated plants. The flowers are frequently disproportionate to the size of the plant; for example, *S. gigantea* produces flowers about a foot in diameter. Except in fanciers' collections and in botanic gardens these plants are rarely cultivated, probably because of their smell.

STAFFER, Paul, French author: b. Paris, 14 May 1844. He was educated at the Bonaparte Lyceum, Paris. He was professor of foreign literature at Grenoble in 1881-83, then accepting a similar chair at the University of Bordeaux. He contributed to the *Temps* and other leading magazines, and is known as an essayist of profound learning and exquisitely finished style. He edited the 'Grands écrivains' series and is author of 'Petite comédie de la critique littéraire de Molière' (1866); 'Shakespeare et l'antiquité' (2 vols., 1883); 'Racine et Victor Hugo' (1886); 'La Grande prédication chrétienne en France' (1898); 'Questions esthétiques et religieuses' (1906); 'Vers la vérité' (1909); 'Les leçons de la guerre' (1915), etc.

STAPLES, stá'plz, Robert Ponsonby, English artist: b. 30 June 1853. He received his instructions in art at the Louvain Academy of Fine Arts (1865-70); at Brussels under Portaels, and at Dresden (1867). In 1869 he visited Paris and exhibited at the Royal Academy, Burlington House (1875). He subsequently passed a year in Australia (1879-80). He served as Art Master of the People's Palace, Mile-end Road (1897). His chief works are 'Guilty or Not Guilty'; 'The Last Shot for the Queen's Prize, Wimbledon'; 'Cardinal Manning's Last Reception'; 'Mr. Gladstone introducing the Home Rule Bill'; 'The Queen and King Edward VII,' etc.

STAPLES, William Read, American jurist and historian: b. Providence, R. I., 10 Oct. 1798; d. there, 19 Oct. 1868. He was graduated at Brown University in 1817, and was admitted to the bar in 1819. He was associate justice of the Rhode Island Supreme Court in 1835-54, and chief justice of that court in 1854-56. He then resigned because of failing health. From 1856 he was secretary and treasurer of the Rhode Island Society, and he was one of the founders of the Rhode Island Historical Society. He was an authority on the history of Rhode Island, and edited

the second volume of the Historical Society's collections, as well as Samuel Gordon's 'Simplicities' Defense against Seven-Headed Policy' (1835). Author of 'Annals of Providence to 1832' (1843); 'Documentary History of the Destruction of the "Gaspé"' (1845); 'Proceedings of the First General Assembly for the Incorporation of the Providence Plantations in 1647' (1847); 'Rhode Island Form-Book' (1859).

STAPLES, Minn., city in Todd County, 120 miles northwest of Minneapolis, on the Northern Pacific Railroad. It has railroad repair shops, and is important as a railroad division headquarters and transfer point. It was settled in 1892. Pop. 2,558.

STAR-ANISE, the fruit of a shrub or small tree from Eastern Asia (*Illicium anisatum*), of the Magnolia family. It has small, but beautiful, fragrant blossoms, in terminal cymes and oblong leaves, which emit, when bruised, the odor of anise. The fruit is a brown capsule, like a star, commonly eight pointed, each ray being a follicle, opening at the top, and enclosing an oval, glossy brown seed. These seeds yield an aromatic oil, which is carminative and stimulative, and although sometimes used therapeutically, is chiefly employed for flavoring foods and liqueurs, having a sweet taste and odor more like fennel than anise. The fruits are burned as incense in the temples of Japan, where the tree is a great favorite with the native gardeners. It is also cultivated in Florida.

STAR-APPLE, the fruit of *Chrysophyllum cainito*, a sapotaceous tropical tree, native to the West Indies. It is about 25 feet high, very ornamental, and has slender branches and very beautiful foliage, the leaves being clothed beneath with golden-yellow hairs. The fruits are berries, about the size and shape of an apple, and vari-colored, white, green, yellow, rose-colored, or purple; it contains a pulp with a pleasant flavor, but unless perfectly ripe is astringent and leaves an intense acidity in the mouth which is difficult to remove. In the centre are eight or 10 cells, each containing a shining brown seed. When cut across, while immature, these cells form a many pointed star in the centre of the fruit.

STAR OF BETHLEHEM, stated in the New Testament to have appeared in the sky at the time of the birth of Christ. At various times since the appearance of Tycho Brahe's star in the constellation Cassiopeia in 1572, the celebrated Nova of that year, it has been suggested that this might be a variable star of long period, though there is nothing now in the vicinity of the place of this star brighter than the 12th of 13 magnitude. Nevertheless, a reported appearance of a bright star in somewhere near that part of the heavens about the middle of the 13th century combined with a more vague account of some similar appearance a little more than 300 years earlier, furnished material for conjecture that these might possibly be former appearances of the star of 1572, giving a period of about 310 or 315 years, which would carry it back three periods more to about the time of the birth of Christ. But as bright stars flame up occasionally, apparently from the collision of dead worlds, there is no scientific reason for doubting the existence of

one at this time; although the idea that it stopped over the stable where the infant Jesus lay must have existed in the imagination of the beholders.

STAR OF BETHLEHEM, a liliaceous herb of the genus *Ornithogalum*, the flowers of which are fancied to resemble the star which located the place of Jesus' birth. The species are natives of the Old World, but two have escaped from gardens and become naturalized in America, especially *O. umbellatum*. It is low, with narrow leaves (the midrib being lighter in tone), which spring from a coated bulb, the flowers are arranged in the plan of threes, and are corymbose and borne on slender, bracted scapes in late spring. The six perianth-segments are nearly equal and separate, and open only in sunshine, the outside of each being pale green with white edges, while the inside of all is pure white. The small bulbs have been eaten in Palestine. Among other species of *Ornithogalum*, is the *O. caudatum* from the Cape of Good Hope, sometimes called onion-lily. Its leaves dry into long tails and its watery bulbs have great vitality unless exposed to severe cold. The satin-flower is the hardy *O. nutans*, with nodding green, white-lined blossoms, and, like *O. narbonneuse*, remarkable for its height (three feet), is a hardy garden bulb.

STAR OF BOKHARA, Order of. See ORDERS (ROYAL) AND DECORATIONS.

STAR-CHAMBER, formerly an English court of civil and criminal jurisdiction at Westminster. It consisted originally of a committee of the Privy Council and was remodeled during the reign of Henry VII, when it consisted of four high officers of state, with power to add to their number a bishop, and a temporal lord of the council, and two justices of the courts of Westminster. It had jurisdiction of forgery, perjury, riots, maintenance, fraud, libel, and conspiracy, and could inflict any punishment short of death. Its process was summary and often iniquitous (especially in the reigns of James I and Charles I), and the punishments it inflicted often arbitrary and cruel. Jurors were punished for finding verdicts against the Crown. It approximated the methods of the Spanish Inquisition, sending for persons, enforcing confessions, and in some instances employing the torture. The excesses of this court brought about its own extinction, for it was abolished by Parliament in 1640. In the modern usage of the term a star-chamber is any secret session of a legislative body, council, board or other organization. In the United States Senate, a star-chamber session is called an executive session.

STAR-GRASS, a name given to several kinds of plants that have star-shaped flowers. Among the ones most widely known in America is the *Hypoxis hirsuta*, a small herb belonging to the Amaryllis family, with a corm or short root-stock, grass-like leaves springing from it, and a slender hairy scape, bearing several stellate three-merous flowers. These are bright yellow, and there are six narrow segments of the perianth, hairy on the outside, and widely spread. One of the lily tribe is the *Aletis farinosa*, a perennial herb; with tuberous rhizomes and bitter fibrous roots, which have been used as a domestic remedy, for intermittent fevers and for colic; whence its other name 'colic

root.^p It is often found in sandy soil, its smooth, lanceolate leaves lying on the ground in a flat rosette, from which arises a tall, stiff stem, terete, and sometimes three feet high, with narrow bract-like leaves. It is crowned by a virgate, spike-like raceme of bell-shaped white flowers, just touched with yellow, and having an appearance of crinkliness like *crêpe*, and as if covered with a rough powder externally. The water star-grass is an aquatic plant (*Heteranthera dubia*) of the pickerel-weed family, its slender forked stems, and grassy floating leaves being found in still water. The flowers are arranged on the plan of threes, and their primrose-colored, stellate rays are widely separated, narrow and acute.

STAR OF INDIA, Order of. See **ORDERS (ROYAL) AND DECORATIONS.**

STAR OF THE OCEAN, Order of. See **ORDERS (ROYAL)—Hawaii.**

STAR QUARTZ, a variety of vitreous quartz, containing thin layers of a foreign substance, which produce the phenomenon of asterism in transverse sections of a crystal when cut en cabochon. Good material of this character has been found in Canada.

STAR OF RUMANIA, Order of. See **ORDERS (ROYAL) AND DECORATIONS.**

STAR SAPPHIRE, a variety of the mineral corundum which exhibits a six-rayed star in transverse sections of a crystal when cut en cabochon. This "asterism" appears to be due to reflections from the surfaces of twinning lamellæ. Fine star sapphires come from Ceylon and are prized as gems. Star Ruby is the rubyled asteriated sapphire.

STAR OF SEVILLE, The ('*La Estrella de Sevilla*'), known also as '*Sancho Ortiz de Roelas*,' the title of a successful adaptation by Trigueros (1802), is commonly attributed to Lope de Vega (1562-1635), but is of doubtful authorship. One scene contains a reference to Vélez de Guevara's '*El Diablo Cojuelo*' first published in 1641. Menéndez y Pelayo believed that the play was originally composed by Lope de Vega, but was rewritten by Claramonte, a contemporary actor and playwright. The oldest edition known is undated, but belongs apparently to the middle of the 17th century. The text is corrupt and often obscure, so that a critical edition is much needed. It is curious to note that a reprint was published in Boston, 1828, by George Ticknor's Spanish teacher, F. Sales, and is the first Spanish play printed in the United States.

'*La Estrella de Sevilla*' is a tragedy, and observes the unities of time and place, peculiarities which give the play distinction in the history of the Spanish drama. It is acknowledged to be a work of unusual beauty, vigorous composition, clear characterization, and intense dramatic interest. The scene is laid vaguely in the stern times of the reconquest, when Spain was engaged in border warfare with the Moors. The dramatist had no historical foundation for the ignoble rôle played by King Sancho the Brave. His object was to depict the stern, unbending honor of Sevillian nobles of a dim past when there was no compromise with duty and honor toward a king, however base and unworthy. But with consummate skill the author represents inflexible justice, personified

in the firm and incorruptible magistrates of Seville, as victorious over the iniquitous monarch. Viewed in this light, the morality of the play, which critics have impugned, is vindicated. The resemblance to Corneille's '*Le Cid*,' based upon a Spanish original, has often been noted. In striking contrast with *Chimène*, *Estrella* retires to a convent rather than accept a lover who, at the request of the king, has murdered her brother. There is probably no ground for the contention that the play contains veiled references to the tragedy that befell Juan de Escobedo at the command of Philip II. Consult '*Obras de Lope de Vega*' (ed. Menéndez y Pelayo, Vol., XI). Lord Holland's translation of fragments will be found in '*Some Account of the Life and Writings of Lope Felix de Vega Carpio*' (London, 1806).

MILTON A. BUCHANAN.

STAR-SPANGLED BANNER, The, a patriotic song composed by Francis Scott Key 14 Sept. 1814, and now recognized throughout the United States as the national anthem, although it is not such in legal fact, Congress having repeatedly rejected proposals—one as recently as 1914—to make a declaration to that effect by resolution. Nearly 100 years after it was written the song was prescribed by formal orders to be played in the army and navy on occasions of ceremony, and that is the extent of its official recognition to-day. Foreigners have long believed '*The Star-Spangled Banner*' to be the fully accented national anthem of America, and in their armies and navies, and on all public occasions when it is desired to honor America in music abroad, the familiar air is played. While many on this side of the water were inclined for many years to discredit the song and to advocate strenuously the claims of '*My Country 'Tis of Thee*,' '*The Battle Hymn of the Republic*,' and even '*Yankee Doodle*' and '*Dixie*,' the standing of '*The Star-Spangled Banner*' was never disputed in other lands.

Even as late as the Spanish War of 1898 the '*Star-Spangled Banner*' had only limited popular recognition and the general disposition at that period, at least in New England, was to elevate '*My Country, 'Tis of Thee*,' to the place of honor. Marching troops in Cuba and Porto Rico, as all the world knows, were partial to '*There'll Be a Hot Time in the Old Town To-night*.' In the Civil War, '*John Brown's Body*' and '*Yankee Doodle*,' on one side, and '*Dixie*' and '*The Girl I Left Behind Me*,' on the other side, were the favorite inspirations of the stalwart men who clashed on a hundred bloody fields. During the War with Germany in 1917-18 debate and difference on the subject of whether we have a pre-eminently preferred national anthem and what that anthem is vanished altogether. The National Star-Spangled Banner Commission laid the groundwork for the change. This commission was organized in Baltimore for the purpose of preparing the centennial celebration of Key's song in September 1914 and for many months before that it conducted an active and widespread propaganda. Patriotic organizations, such as the Sons of the Revolution, the Society of the War of 1812, and others, co-operated with enthusiasm and did much to develop pub-

lic opinion. No other candidate for acceptance as the national anthem had this systematic and vigorous backing, and no other writer of an American patriotic song has had so many honors paid to him as Key, for whom Congress has erected an imposing sculptured memorial in Fort McHenry and whose linaments are preserved in public statuary as far from the scene of his labors as San Francisco. The incidence of war so soon after this propaganda caused it to have a maximum effect.

'The Star-Spangled Banner' was composed by one of the best of the American types. Key was poet, scholar, lawyer, public official and churchman, and member of a distinguished family. He wrote 'The Star-Spangled Banner' in a burst of inspiration. It was written in a moment of acute national stress and expressed, as it does still, the characteristic feelings of the country—not desiring to provoke war, but rising with determination to take arms in defense of the national honor when a crisis required it. In literary form it is far superior to most patriotic songs, and even without the music would find wide popularity on its merits as a poetical composition.

It struck the popular fancy at first and has held it in large measure ever since. Key had the words printed in hand-bill form in the office of *The Baltimore American*, and distributed on the streets of the delivered city in September 1814, before the British fleet which had been beaten off from Fort McHenry had gotten out of the Chesapeake. It was sung on the stage of the famous Holliday Street Theatre in Baltimore and taken up with intense eagerness by the people there and throughout the nation. Few incidents in our national history have been beclouded by so much misconception of fact as the origin of this anthem. The most common error, which has had an unfortunate habit of creeping into print, is that Key composed the words while he was a prisoner of war on the British fleet which attacked Fort McHenry. Key was not a prisoner of war, but had gone to the fleet on the cartel ship *Minden*, used by the American government in negotiating exchanges of prisoners, for the purpose of obtaining the release of a civilian, Dr. William Beanes of Upper Marlborough, Md., who was being detained because he had caused the arrest of British marauders. As Key reached the fleet, when the attack on Baltimore was about to begin, he was kept behind the British lines until it was over in order that he might not convey information of the impending movement. He was treated with the utmost consideration and was promptly released when the attack ended. When he was rowed ashore on the morning after the bombardment he had in his pocket, scribbled on the back of an old letter, the draft of the song which has become so famous since. The original manuscript is owned by Henry Walters, owner of the Walters Art Gallery. The flag whose "broad stripes and bright stars" burst upon Key's enraptured vision on that September morning of 1814 is preserved in the National Museum at Washington, D. C.

The words of the song follow:

THE STAR-SPANGLED BANNER.

Oh! say can you see by the dawn's early light,
What so proudly we hail'd at the twilight's last gleaming,
Whose broad stripes and bright stars through the perilous
fight,
O'er the ramparts we watch'd were so gallantly streaming?
And the rocket's red glare, and bombs bursting in air,
Gave proof through the night that our flag was still there!
Oh! say, does the star-spangled banner yet wave
O'er the land of the free and the home of the brave?

On the shore dimly seen through the mist of the deep,
Where the foe's haughty host in dread silence reposes,
What is that which the breeze o'er the towering steep,
As it fitfully blows, half conceals, half discloses?
Now it catches the gleam of the morning's first beam,
In full glory reflected, now shines in the stream;
'Tis the star-spangled banner. Oh! long may it wave
O'er the land of the free and the home of the brave.

And where is that band who so vauntingly swore,
Mid the havoc of war and the battle's confusion,
A home and a country they'd leave us no more?
Their blood has wash'd out their foul footsteps' pollution;
No refuge could save the hireling and slave
From the terror of flight, or the gloom of the grave,
And the star-spangled banner in triumph shall wave
O'er the land of the free and the home of the brave.

Oh! thus be it ever, when freemen shall stand,
Between their lov'd home and war's desolation;
Blest with victory and peace, may the Heaven-rescued land
Praise the power that made and preserved us a nation.
And conquer we must, when our cause it is just,
And this be our motto, "In God is our trust."
And the star-spangled banner in triumph shall wave
O'er the land of the free and the home of the brave.

STAR-THISTLE, one of the European plants of the genus *Centaurea* (q.v.). They are not true thistles, but are closely allied composites. *C. calcitrapa* is an annual, much branched, and spreading weed sparingly naturalized in America. It has one to two-pinnatifid, serrulate, spiny leaves, the upper one sessile and clasping. The flowerheads are purple, small and rayless, and have an ovoid receptacle surrounded by ovate involucre bracts, the outer being long and spreading, and tipped with stout spines. The common name is said to be derived from a fancied resemblance of the spiny involucre of the yellow flowered star-thistle (*C. solstitialis*), to the weapon called "morning-star," an iron ball with short spikes.

STAR OF THE WEST. At sunset 5 Jan. 1861, the merchant steam-vessel *Star of the West* sailed from New York to supply and reinforce Major Robert Anderson, at Fort Sumter, Charleston Harbor. She was commanded by Capt. John McGowan, was unarmed, and carried a large quantity of supplies for Anderson, as well as Lieut. C. R. Woods, United States army, with four officers and 200 artillery recruits. She reached the outer bar of Charleston Harbor before daylight 9 January and as the harbor lights were out, put out her own and groped in the dark until nearly daylight, when, guided by the light on Fort Sumter, she stood in. The South Carolina authorities had been notified of her coming by Secretary Thompson of President Buchanan's Cabinet, and a vessel was lying off the main channel watching for her, and when she was seen gave signal-lights of warning to the Confederates on Morris Island, and then ran up the harbor, the *Star of the West* following, as soon as it was light, and steaming up the main channel for Fort Sumter. She flew the United States ensign at the fore and went on without interruption until within one and three-quarters miles of Forts Sumter and Moultrie, when she was fired upon by a battery near the north end of Morris Island and about five-eighths mile distant. She ran up a

garrison flag, to which no attention was paid, save to increase the rapidity of the Confederate fire, which was kept up on her from Morris Island, with an occasional shot from Fort Moultrie. McGowan was powerless to defend himself, and no assistance came from the guns of Fort Sumter, as Major Anderson had not been notified of this expedition for his relief. Therefore McGowan turned his vessel seaward, after 17 shots had been fired at it, two of which had struck it, and returned to New York on 12 January. This firing on the flag of the United States was the first overt act in the Civil War. At the South there was great exultation that the flag of the Union had been insulted; at the North it produced but little excitement. Consult 'Official Records' (Vol. 1).

STARA-ZAGORA, Bulgaria (Turkish name *ESKI-ZAGRA*), a town in Eastern Rumelia, capital of the department of the same name, 45 miles south of Tirnova, at the foot hills of the Balkans. Rose oil is the town's principal industry. It has also mineral springs and its commerce is helped by its location at the junction of the principal passes of the Balkan Range. In the neighborhood, in July 1877 the Russians were defeated by the Turks under the command of Suleiman Pasha. Pop. about 22,000.

STARCH, a proximate principle exclusively of the vegetable kingdom with the formula $n C_{12}H_{20}O_{10}$. The value of n has not been determined but all experiments go to show that it is large — not less than 100, and that, therefore, the molecular weight of starch is at least 32,400. It is found in almost every plant at some period of its life-history, and is especially abundant in wheat, potatoes, arrowroot and other similar kinds of vegetation, and forms a very large and important part of the food of man and the herbivorous animals. It occurs in the ovule of the seed, in the cotyledons of the embryo, in the pith, the bulbs, stems and notably in the roots and tubers of certain families of plants, as the potato, sweet potato, cassava, etc. The starch granules are found in the growing plant in the protoplasm of the chlorophyll corpuscles, varying according to the time of day, being in greatest numbers toward evening and fewest in the morning, sometimes disappearing entirely during the night. Appearing at first as simple points, they gradually increase in size, so that eventually they fill completely the chlorophyll corpuscle, the latter appearing as simply an envelope for the starch. The starch granules grow and increase in size only when in contact with protoplasm and under conditions of exposure to light at a favorable temperature and in the presence of carbon dioxide. These granules are of widely varying sizes in different plants, ranging from a diameter of 0.0069 inch in the canna and 0.0055 inch in the potato, to 0.0003 inch in the parsnip and 0.0002 in the seeds of the beet. Starch appears to be formed in plants in greatest quantity when there is a large supply of nutriment, and it disappears when the nutriment becomes deficient. The amount of starch in various alimentary substances is exhibited in the table following.

Starch is a soft, white, shining powder, insoluble in cold water, alcohol or ether; under the microscope it is seen to consist of granules, each of which is formed of a series of stratified envelopes concentrically arranged round a com-

Name of substance	Starch in 100 parts

Potatoes (air-dried).....	16 to 23

mon nucleus, the outer ones being the denser. Inasmuch as these layers or envelopes are of variable thickness they cause the granule to assume more or less a flattened ovoid form. Occasionally there are two nuclei within the outer envelope, each surrounded with its own series of concentric layers. The outer layer is the first formed and is known as "starch cellulose"; the interior is called "granulose." These two substances may be separated by appropriate chemical action. Starch dried at ordinary temperatures always retains an amount of water varying from 12 to 18 per cent; but by drying in a vacuum over sulphuric acid and gradually raising the temperature to 212° F. it may be obtained perfectly free from water; but if it be boiled with water the starch granules are swollen and broken up, so that on cooling, a stiff, gelatinous mass, starch-paste, is produced; on largely diluting this paste with water, the swollen granules for the most part subside, but a considerable quantity of starch remains in solution. By boiling starch mixed with a quantity of water, under pressure, at a temperature of about 300° F., it is mostly dissolved, and on filtering the liquid and allowing it to cool small granules of starch are deposited, which are slightly soluble in cold water, and are at once dissolved by water heated to 160°. This modification of starch is known as soluble starch. The simplest method of making soluble starch is to dissolve it in hot glycerine. Starch may be detected by boiling the suspected substance with water, cooling and adding tincture of iodine, when, if starch be present, a fine deep blue color is produced; this color is dissipated by heat or by substances such as alcohol, ether, etc., which dissolve and so remove the iodine.

Nitric acid acts on starch in different ways, according to the strength of the acid used and the temperature. Cold concentrated nitric acid forms a substitution product, in which one hydrogen atom of the starch is replaced by the group NO_2 . A mixture of concentrated nitric and sulphuric acid gives rise to the formation of a dinitro-substitution product, in which two atoms of hydrogen are replaced by the group NO_2 twice. Hot nitric acid converts starch into oxalic, malic and acetic acids. Acted upon for 24 hours by a 12 per cent solution of hydrochloric acid, the starch becomes soluble in water without forming a paste.

Preparation of Starch.—With regard to the purposes to which starch is applied, the various kinds may be divided into (1) starches used for food and (2) starches used for laundry and other industrial purposes, though certain kinds are extensively used under both of these heads. In their chemical relations all varieties of starch are identical, but in their physical constitution and microscopic structure they present

marked differences, and they also vary much as regards digestibility and suitableness as articles of food. The size of these granules and the arrangement of layers differ in every different species of plant, and, therefore, the source of any particular starch is readily determined by microscopic examination. Starch may be purified by freezing a 1 per cent mixture with water and melting the ice. The starch settles and the liquid retains the impurities.

The food starches embrace arrowroot, touselmois, sago and tapioca. Corn-starch, which has an enormous sale, is simply the starch of Indian corn or maize separated mechanically from the grain. The process most commonly in use in the United States is known as the sulphur dioxide process. The grain is steeped in a 1 per cent aqueous solution of sulphur dioxide at a temperature of 250° to 300° F. for from two to four days. The swelled grains while wet are then crushed between cylinders under a flow of water, washing the mass through a cylindrical sieve so as to separate out the husky matter. The milk-like fluid which contains the starch in suspension passes through the sieve and is run along a series of gently inclined surfaces, on which the heavier granules are deposited, the lighter and finer particles being carried with nitrogenous matter into settling-tanks. The deposit which accumulates in the settling-tank is purified by repeated straining and settling, and the separated starch is dried by gentle artificial heat, when it crumbles to a powder, and as such it is packed for the market.

Starch for industrial purposes is obtained also from potatoes, wheat and rice, and sago starch is extensively employed for other than food purposes. Starch from many different substances finds occasional or limited employment. Potatoes affected by disease yield as pure and useful a starch as sound tubers, but much less in proportion to their weight, as the disease usually results in the transmutation of starch to sugar. On a small scale the preparation of starch from potatoes is a simple operation. The tubers have simply to be thoroughly washed to free them from all earthy impurity, then rasped down to a fine pulp in a tub of water and allowed to settle, when the starch will fall to the bottom and the greater part of the skin or husk will float on the water. By repeated washing and settling of the starchy deposits the starch may be obtained in a condition of purity, and it may then be dried by gentle heat for preservation and use. On the manufacturing scale, machinery of various kinds is adapted for performing the several processes of steeping and washing, straining out of stones, rasping, straining, settling, purifying, draining and drying which the potatoes undergo. Some manufacturers pass the raspings through a grinding mill, resulting in an increase of starch product by 8 to 12 per cent. Beyond its use in industrial pursuits in common with other starches, potato-starch is much employed for making imitation sago, for adulterating and as a substitute for the more costly food-starches, for preparing starch-sugar and as a source of potato-spirit.

Wheat-starch is prepared by two distinct processes. By the first and old method the grain is subjected to a process of fermentation

whereby the gluten or nitrogenous constituent of the wheat is rendered soluble and the remainder of it loses its adhesive property, and in this condition the starch is easily separated out by a washing wheel or drum. By this process the greater part of the gluten is wasted, and a smaller yield of starch is obtained than can be secured by the more recent system of Martin. The principle on which the latter proceeds can be easily illustrated by making a dough of flour, placing it in a muslin bag and squeezing it under the water, when the starch exudes mingling with the water and settling as a sediment, leaving within the muslin a gray semi-elastic mass consisting chiefly of gluten. In this way the gluten is saved and can be utilized for cattle-feeding, etc. The production is two pounds of starch for each pound of gluten. By whatever process prepared, wheaten starch is purified by repeated washing and settling, and dried by gentle heat, and on drying it assumes the columnar structure by which it is familiarly known.

In the preparation of rice-starch, a variety preferred for laundry purposes, the grain has to be steeped in a slightly alkaline solution on account of its peculiarly hard and horny envelope of gluten. In addition to being extensively used in laundries, starch is largely consumed in the manufacture of dextrin (q.v.), and it is also employed as a thickener in calico-printing, and in the finishing of bleached and printed calicoes. Placed in a 2 per cent solution of soda or potash the granules swell, forming a tenacious paste used by photographers for mounting prints and for many other purposes. Dry starch finds a valuable minor adaptation in dusting molds in metal-casting, besides being applied for many miscellaneous purposes.

Statistics.—In the United States in 1914 there were 82 starch factories, having an invested capital of \$12,070,000. There were 1,780 persons employed and the total value of the product for the year was \$13,996,000. In this production New York ranked first, Indiana second and Ohio third. The total quantity of starch manufactured was 620,764,347 pounds. Of this total, 574,247,697 pounds were made from Indian corn, 23,540,472 pounds from potatoes and 22,976,178 pounds from all other materials. A very large quantity of starch was made by the seven glucose factories previous to its conversion into glucose (q.v.). No account is made of this in the figures given, as the product did not appear in the markets as starch.

STARFISH, any echinoderm of the group *Asteroidea* (see ECHINODERMATA), in which a pentagonal disc forms the central body, whence radiate five or more pointed arms, containing prolongations of the stomach, as well as digestive glands, reproductive organs, etc. The mouth is on the inferior surface of the disc and the vent (when one exists) is on the upper surface. The exoskeleton consists of a mosaic of limy plates united and covered by a leathery, usually reddish-brown skin, forming a pliant armor. The plates of the disc are similar to those of the "cup" of crinoids (q.v.) and similar echinoderms. Those of the arms form along the floor a groove carrying the ambulacral water-vessels and tube-feet. The exterior of the plates, except in the ambulacral grooves, is studded with tubercles, each bearing a spine,

giving the starfish a generally spiny appearance. Studding the skin among the spines are numerous branchial papillæ and the usually three-jawed, flexible-stalked pedicellariæ, which continually bend about and by their snapping pick up and remove accumulated waste matter from the respiratory surface of the animal. So independently do they act that for many years they were considered to be parasites. The alimentary canal is simple, with a pair of large cæcal digestive glands reaching into each arm. (The nervous, blood and water-vascular systems conform to the plan described in the article ECHINODERMATA). Distinct eye-spots are present at the tips of the rays in most species, the large orange-colored spot which is popularly called the "eye" of the starfish being in reality the madreporic plate, by means of which water is admitted to the ambulacral system. In starfishes the sexes are usually separated and the eggs fertilized in the water. Development takes place with a metamorphosis, the larval stage being free-swimming, provided with ciliated bands and processes, and known as the bipinnaria. The body of the young starfish forms within the body of the larva, only a small portion of which develops directly into the starfish, the remainder being simply absorbed to nourish it.

Locomotion is accomplished by means of the thousands of tube-feet arranged in double rows on the under side of each arm. These successively extend, attach themselves, contract, let go and reach forward again, hundreds acting together to draw the body slowly but continuously onward. The individual feet are extended by means of water forced into them by the contraction of the ampullæ, with which each is provided, and contracted by their own musculature, which forces the water back into the now relaxed ampulla, the supply of water in any part being regulated through the madreporic plate and the system of canals and polian vesicles. Besides the sexual mode of reproduction starfishes possess the power of regenerating lost parts developed to so great a degree that it amounts to a sexual reproduction. When handled or injured they will often automatically cast off an arm or even all of the arms close to the base. Not only will the disc regenerate any number or all of its arms when lost, but in some cases the single arms will develop new discs, thus producing several individuals from one. Experimental cuttings of starfishes has shown how bifurcated or extra arms may be produced. As their only natural enemies are bottom-feeding fishes of the cod family, and as it seems probable that one or more arms could thus often escape capture, this capacity for regeneration (q.v.), combined with their tenacity of life and enormous fecundity, probably accounts for the surpassing numbers in which they sometimes occur.

All starfishes are marine and most of them live in comparatively shallow water, though a few extend to great and many to moderate depths. As fossils they occur in most formations from the Cambrian upward, but are much less numerous than the sea-urchins, being less well adapted by their structure for preservation. While the number of arms is generally five, or some multiple of five, some genera bear irregular numbers as 13 in *Solaster*, 9 to 13 in *Brisingsa*, or upward of 20 in *Heliaster*, while

a few, as *Culcita* and *Asteriscus*, are pentagonal and nearly without trace of arms.

Starfishes are voracious creatures which feed for the most part upon mollusks, including such large bivalves as oysters. The manner in which they accomplish this apparently impossible feat is very remarkable. By means of the suckers at the ends of the tube-feet the starfish attaches part of its arms to each valve of the oyster and by a steady continuous traction sooner or later so weakens the adductor muscle of the latter that the valves gape open. As the mouth is too small to admit the body of the oyster the stomach is protruded and, enwrapping its prey, the soft body is gradually sucked through the mouth. Small gastropods may be taken into the mouth entire. Many species of starfishes live on the bottom in vast shoals, and, although sluggish creatures, they often migrate to new feeding grounds, moving over the ground steadily in a definite direction.

The best-known starfishes of our Atlantic shores are the *Asteracanthion vulgaris* and *A. forbesii*, the former chiefly north, the latter south of Cape Cod, though both are found in Vineyard Sound and the neighboring waters. They are nearly alike, reach a diameter of 12 or 15 inches and extend from low water to considerable depths. Both species congregate in great numbers on mussel and oyster beds, often committing great havoc on the latter. They are removed from the latter by the boatload by means of dredges and tangles and cast ashore. Formerly the oystermen broke them into pieces, which were cast into the water in expectation of killing them, with the result that their numbers were increased greatly. The smooth starfish (*Cribrella sanguinolenta*) is a very pretty, small, shallow water species with five long, round, nearly smooth arms and a color which varies from purple to yellow and pink. It is most abundant north of Cape Cod and is remarkable in utilizing the sides of the mouth as a brood pouch in which the young are carried. *Echinaster sentus* is a related southern species with rough spinous arms. *Croosaster papposus* is common in a few fathoms of water on the New England coast. It has a very broad body disc and flattish arms, which vary from 12 to 15 in number. *Luidia clathrata* and *Astropecten articulatus* are flat, very brittle, five rayed starfishes with the upper surface very densely covered with small spines and the arms margined with large plates and a fringe of spines. Both occur on the south Atlantic coasts, occasionally as far north as New Jersey. Many interesting species are dredged in deeper water or are sometimes thrown ashore during storms, and others occur in the Gulf of Mexico in shallow as well as deep water. One of these is the massive, heavily-armored, rigid *Pentaceros reticularis*, the species commonly sold in shell shops at the seaside resorts and the largest starfish of the Atlantic Coast. The Pacific Coast fauna is much richer and more varied, among the species being the gigantic *Asterias giganteus*, over two feet in diameter and six-rayed, the 10-rayed *Solaster decemradiatus*, the flat, granulated, bright-red *Mediaster aequalis*, the thick, flat, pentagonal, great-spined *Nidorella armata*, and the nearly armless and very small *Asterina miniata*. University of Pennsylvania.

STARGARD, stâr'gärt, a town in Pomerania, Prussia, 21 miles southeast of Stettin, on the Ihna River. It consists of three parts, the main town and two suburbs. It was formerly a fortified town; but of the ancient walls only the gates remain, the rest having been replaced by promenades. There is a monument commemorating the Franco-Prussian War. The buildings deserving notice are the old town-house, churches, gymnasium and orphan asylum. Stargard has a law court and government offices, there is a brisk trade in agricultural produce, iron foundries, machine-shops, soap and oil factories, distilleries and roofing factories.

STARK, John, American soldier: b. Londonderry, N. H., 28 Aug. 1728; d. Manchester, N. H., 8 May 1822. In 1755 he became a lieutenant in Major Rogers' rangers and fought through the French and Indian struggles around Lakes George and Champlain. In 1775 he joined the Continental army, was appointed colonel and fought at Bunker Hill and later at Princeton and Trenton. After the retreat of General St. Clair and the capture of Ticonderoga by the British, Stark was put in command of a force of "Green Mountain boys," that met and defeated an English detachment under Baum at Bennington 16 Aug. 1777. A supporting British force under Breymann was also defeated. These events paralyzed the British operations and led to the surrender of Burgoyne at Saratoga. He was promoted brigadier-general, and continued in active service until the end of the war. Consult Everett, E., 'John Stark' (New York 1902); Stark, C., 'Memoir and Official Correspondence' (Concord, N. H., 1860).

STARKEY, stâr'ki, Thomas Alfred, American Protestant Episcopal bishop: b. Philadelphia, Pa., 1819; d. East Orange, N. J., 17 May 1903. He was educated as a civil engineer and engaged in that profession in 1839-45, after which he studied theology and in 1848 he was ordained to the priesthood. He was rector of Christ Church, Troy, N. Y., in 1850-54, of Saint Paul's, Albany, N. Y., in 1854-58, of Trinity Church, Cleveland, Ohio, in 1858-69 and was in charge of the church of the Epiphany, Washington, D. C., in 1869-72. He was called to Saint Paul's Church, Paterson, N. J., in 1877 and in 1880 he was consecrated bishop of northern New Jersey.

STARKEY, Thomas Albert, Canadian physician and bacteriologist: b. Cheshire, England, 1872. He was graduated in medicine at the University of London in 1894, and later spent some time in the London hospitals. He was for a number of years engaged in research work in India, seeking methods for the prevention and cure of cholera. He was engaged at the Imperial Research Laboratory, Bombay, in 1899-1901, and afterward superintended the sanitary work in the districts of

Satara and Poona, India. He was bacteriologist to the London county council on his return to England, and in 1902 accepted the chair of hygiene at McGill University. He became a member of the Royal Sanitary Institute, London, in 1906; and in 1910 was elected the first president of the Canada Public Health Association. He is author of many papers and reports on his specialties.

STARKVILLE, Miss., city and county-seat of Oktibbeha County, 115 miles northeast of Jackson, on the Illinois Central and the Mobile and Ohio railroads. The Mississippi Agricultural College is located here. There are stock-raising, cotton and lumber interests, and cotton and cottonseed-oil mills. Pop. 2,698.

STARLING, a field-bird of the family *Sturnidae*, known by the compressed sharp bill, the long and pointed wings and the short tail. The tarsi are stout and covered in front with broad scales. The toes are also elongated and strong, the hinder toe being largely developed. The common starling (*Sturnus vulgaris*) is a well-known European bird, commonly seen in large flocks, particularly in marshy districts. The general color is dark green, tinted with purple hues, and with metallic lustres. The shoulders are brown or buff, the wing-coverts edged with pale brown and the general plumage spotted with buff. The breast feathers are elongated and pointed; the beak is yellow. In the second year of life the characteristic colors consist of the adult colors just described, these, however, being of generally lighter hue, whilst the general surface is marked with light-colored spots. The first year's birds are brown. The females are less brilliantly colored than the males. The nest is loosely constructed, and is generally found in some ruined wall or castle, or in a hollow tree. The five eggs are pale blue. The young are tended by both parents. The food of the starling consists of insects, and these birds haunt domestic animals to get the insects that prey upon them. They often perch on the backs of cattle in search of the insect larvæ that burrow in the skin; and pluck wool from sheep for the purpose of lining the nest. They also eat mollusks, worms and vegetable matters, and they have been known to strip whole shrubberies of their leaves. The common starling is found throughout Europe, Africa and most of Asia, and is migratory. Starlings are viewed with great favor in many districts, are caught to be kept in cages, and may be taught to speak, to mimic sounds with great distinctness and to whistle tunes. Their natural note is a peculiar, indrawn, clear and pleasing whistle. They have been acclimatized in the neighborhood of New York, where they were introduced in 1890; since which time they have spread over most of the Northeastern States. Various more or less similar or related birds are called starlings in India and Australia. Consult Forbush, E. H., 'The Starling' (in *Massachusetts State Board of Agriculture* 58th annual report, Boston 1915); Leydekker, R., 'Standard Natural History' (London 1895); Newton, 'Dictionary of Birds' (New York 1896).

STARNINA, Gherardo, gâ-râr'dô stâr-nê'nâ, Italian painter: b. Florence, 1354; d. 1407. He was a pupil of Antonio Veneziano. After painting the history of Saint Nicholas and Saint Anthony, on the ceiling of the Castellani Chapel

in Santa Croce, he was forced for political reasons to take refuge in Spain. There he worked for the king and others, returning to Italy with considerable wealth (1387). He made many frescoes but little of his work remains save the 'Death of Saint Jerome' in the church of Santa Maria del Carmine.

STARR, stâr, Frederick, American anthropologist: b. Auburn, N. Y., 2 Sept. 1858. He was graduated at Lafayette College in 1882 and from 1889-91 was in charge of the department of anthropology at the American Museum of Natural History; in 1888-89 was registrar of Chautauqua University; 1892-95 was assistant professor, and since associate professor of anthropology in the University of Chicago. Later he traveled extensively, making special studies in anthropology and ethnography, in Mexico; in Central Africa, 1905-06; in the Philippines 1908; in Japan, 1909-10; and in Korea, 1911. He published 'First Steps in Human Progress' (1895); 'American Indians' (1899); 'Indians of Southern Mexico' (1899); 'Strange People' (1900); 'The Ainu Group at the Saint Louis Exposition' (1904); 'The Truth About the Congo' (1907); 'In Indian Mexico' (1908); 'Filipino Riddles' (1909); 'Japanese Proverbs and Pictures' (1910); 'Congo Natives' (1912); 'Liberia' (1913); 'Mexico and the United States' (1914).

STARR, Moses Allen, American neurologist: b. Brooklyn, N. Y., 16 May 1854. He was graduated at Princeton University in 1876 and received his medical degree from Columbia University in 1880. He became editor of the *Psychological Review* and *Journal of Nervous and Mental Diseases*, and published 'Familiar Forms of Nervous Disease' (1893); 'Brain Surgery' (1895); 'Atlas of Nerve Cells' (1897) and lectures on 'Diseases of the Mind' (1898), and 'Diseases of the Nervous System' (1899); 'Nervous Diseases, Organic and Functional' (1913); besides numerous articles to medical journals and chapters to textbooks on mental and nervous diseases. He received from Princeton the degrees of Ph.D., 1884; LL.D., 1899, and from Columbia, Sc.D., 1904. At Columbia University he was lecturer, 1887-89; professor, 1889-1915 and since professor emeritus of neurology.

STARRY CROSS, Order of. See **ORDERS (ROYAL) AND DECORATIONS**.

STARS, a designation familiarly applied to all the heavenly bodies which look like points of light. This designation includes five of the planets, Mercury, Mars, Venus, Jupiter and Saturn. In scientific language the term is applied only to those bodies which seem fixed on the celestial sphere, and are, therefore, termed *fixed stars*. These are immense incandescent bodies, scattered through the immensities of space at distances which beggar all our conceptions. In accordance with the general plan of the present work, we begin with a study of the stars as they appear to us, and then pass to the consideration of their actual constitution and situation in space. We shall, therefore, suppose the reader to scan the heavens at night while we point out certain features of the scene of grandeur then presented to his vision.

The first feature to be noticed is the great diversity in the brightness of the stars, or, to use a technical expression, in their *magnitudes*. These range all the way from that of the brightest stars down to the point of invisibility to the naked eye. The smallest telescope will show scores of stars too faint to be seen without its aid, and the greater the power of the instrument the greater the number that will be brought into view, without any limit yet known.

The ancient astronomers divided the stars into six orders of magnitude, called the first, second, etc. The 15 or 20 brighter stars were classified as of the first magnitude, those a grade below them as of the second, and so on, until they came to the sixth, which comprised the faintest stars visible to the unaided eye. All these stars are now called *lucid*; fainter ones *telescopic*. In modern times the preceding system of magnitudes has not only been extended to the telescopic stars, but has been arranged on a plan which gives greater precision, and enables us to designate the exact measure of the light which we receive from a star by its magnitude. The magnitudes of stars are now designated to tenths, or, to give greater precision, even to hundredths of a magnitude. Thus we have stars of magnitudes 3.0, 3.1, 3.2, etc. These numbers are arranged on a diminishing scale of light, so that a difference of one magnitude corresponds to the multiplication or division of light by a number very near 2.5, or, more exactly, the number whose logarithm is 0.4. This means that a star of magnitude 3.0 is about two and a half times as bright as one of magnitude 4.0; this again about two and a half times as bright as one of magnitude 5.0, etc. The exact scale is such that a star of the first magnitude is precisely 100 times as bright as one of the sixth, while the latter is 100 times as bright as one of the 11th, so that an increase of five units in the scale of magnitude corresponds to a division of the light by 100.

Careful examination will also show that the stars of each magnitude are several times as numerous as those of the brighter magnitudes. There are three or four times as many stars of the fourth magnitude as of the third; three or four times as many of the fifth as of the fourth and so on in nearly geometrical progression. But when we pass to the stars invisible to the naked eye the progression is not so rapid. Yet its common ratio does not fall below two at any point yet known. The result is that the stars of the fainter magnitudes are to be counted by millions. The faintest stars visible in the largest telescopes are about of magnitude 17 or 18.

Another familiar feature of the sky is that the stars are not scattered uniformly, but that the brighter ones appear to be collected to a greater or less extent into constellations. There is, however, no precise dividing line between one constellation and another. The irregularity is such that the number of constellations is somewhat arbitrary. The fainter the stars the less marked is the division into constellations. The telescopic stars cannot be divided into constellations at all. See **CONSTELLATIONS**.

Careful observation shows that the stars differ slightly in color. It is true that the colors are less marked than those of natural objects, there being no such red as the ruby and no such bright green as the emerald among the

stars. But there is a regular gradation from a yellowish red through white, to a well-marked, bluish tint. These differences of color are supposed to indicate different degrees of temperature of the stars, or different periods in their growth and development.

Number of Stars.—The whole number of stars in the heavens, visible to the naked eye, is about 5,000. As one-half of these are necessarily below the horizon at any one time, it follows that not more than 2,500 can be seen at once. But this is greater than the actual number visible under ordinary conditions, because small stars near the horizon are rendered dim or invisible by the thickness of the air through which we see them. Practically, it is not likely that more than 2,000 stars can ever be seen at once by the best eye, unless at elevated points where the air is very clear down to the horizon.

Up to the present time it has been impossible to make anything like an enumeration of the telescopic stars, because, as we have already said, every increase in the power of the telescope brings out new stars that otherwise would be invisible. There is, however, no doubt that the stars visible in a large telescope are to be counted by tens of millions. It is now found that stars can be photographed with a large telescope which are so small that the eye would not perceive them in the telescope itself. It is probable that the whole number found on the best photographic plates amounts to more than 100,000,000. But we must not suppose that this number would actually comprise all the stars in the sky. Although in some directions we seem to have reached the limit of the visible stars, we do not know, when the entire heavens is considered, how many fainter stars there may be for every one that can be photographed. A very recent estimate fixes the total number of the stars at 1,600,000,000, but this is as yet necessarily very uncertain.

The Milky Way.—Another feature of the sky connected with the stars is the Milky Way or Galaxy. This really stupendous though not striking object can be seen at some hour of any night in the year, its position in the sky depending on the season. In our latitudes it is quite near, partly below the horizon during the evenings of May, and is then not readily seen, but even then it may be seen later in the evening. At the proper time, on any night, it passes nearly through the zenith, spanning the heavens like a complete arch, resting on two opposite points of the horizon.

Galileo, pointing his first telescope to the sky, found that this object was composed of congeries of stars too faint to be separately visible. This fact has been abundantly proved by modern observations. A very little study of the sky without a telescope will show that the milky light of these stars is by no means uniform, but is frequently gathered into clouds. These show that the Milky Way is in part made up of vast groups or collections of stars, rather irregular in form. The aspect of the Milky Way is also very different in different parts of its course. One of its most remarkable features is best seen in summer and autumn. It will then be noticed that, in the region of the zenith, the Milky Way seems to be divided into two separate streams with a comparatively dark space between them. This seeming cleft extends toward the south, nearly to the celestial

equator, where one of the streams branches off toward the west and comes to an end, while the other continues on its course. It will also be noticed that at some points of its course the Galaxy is narrow and well defined, while in others, notably in the extreme south, it is wide and diffuse.

Many astronomers have occupied themselves in making photographs of various portions of the Milky Way. Barnard has used a large camera for this purpose, and, in several observatories, the largest telescopes have been so employed. One curious feature is brought out by these photographs. In that part of the Milky Way which in autumn is seen between the celestial equator and the southern horizon, numerous clefts and vacant spaces occur, as though there were actual openings through the mass of stars. This fact seems to show that the thickness of the Milky Way, or the distance through which the line of sight extends when we look at it, is less here than elsewhere. Going farther south, into regions invisible in our northern latitudes, other vacant spaces are found, known as *coal-sacks*. But it is found that stars really exist in these spaces, though they are comparatively few and faint.

Another feature of the southern hemisphere comprises two patches of light called the Magellanic Clouds. These are situated at some distance from the Milky Way, and yet seem to be of the same general nature as the latter. They may be described as two outlying collections of very faint stars.

It is found by careful observation and count that the stars of any magnitude seem to be rather thicker in the region of the Galaxy than elsewhere. The smaller the stars the greater the thickness in and near the Galaxy becomes, so that it is probable that a large majority of the very faint stars belong to the Milky Way. Several other peculiarities connected with stars of the Milky Way will be better understood after we have described certain varying characteristics of the stars.

Naming the Stars.—Most of the brighter stars, not only those of the first and second magnitude, but a few remarkable ones of fainter magnitudes, had special names assigned to them in ancient and mediæval times. The oldest and best known of all these names is Arcturus, which is found in the book of Job. The names of Castor and Pollux were also assigned in classic antiquity to the two brightest stars in the constellation Gemini, or the Twins. But most of these special names are derived from designations given by the Arabs, which were supposed to express some peculiarity of the star. There are also quite modern names, *Polaris*, for example, which designates the Pole Star.

During the past three centuries most of these names have been, to a greater or less extent, replaced by a system of designating the brighter stars in all the constellations, which was introduced by Bayer about 1600. He assigned to the principal stars in each constellation the letters of the Greek alphabet, alpha, beta, gamma, etc. Commonly the first letter of the alphabet is assigned to the brightest star, and the progress of the letters indicates, to a certain extent, the successive orders of brightness in the same constellation. But this rule was not uniformly carried out; frequently the successive letters

taken in alphabetical order designate the stars which follow each other in position. For example, in the familiar constellation of the Great Bear, the first six letters of the alphabet are applied to the consecutive stars which make up the Dipper. The Greek alphabet not being sufficient for all the stars, letters of the Roman alphabet are used when the Greek one is exhausted. Flamsteed, Astronomer Royal at Greenwich, two centuries ago adopted the plan of numbering the stars in each constellation. Any such system, however, is imperfect, and, taken altogether, there is a lack of uniformity in the method of designating the stars, except the brighter ones. The following are a few of the brighter and best-known stars which have well-known names.

Individual name	Name on Bayer system
Alcyone	Eta Tauri
Aldebaran	Alpha Tauri
Algol	Beta Persei
Antares	Alpha Scorpii
Arcturus	Alpha Bootis
Bellatrix	Gamma Orionis
Betelgeuse	Alpha Orionis
Canopus	Alpha Argus (Carinae)
Capella	Alpha Aurigae
Castor	Alpha Geminorum
Fomalhaut	Alpha Piscis Australis
Mira Ceti	Omicron Ceti
Mizar	Zeta Ursae Majoris
Polaris	Alpha Ursae Minoris
Pollux	Beta Geminorum
Procyon	Alpha Canis Minoris
Regulus	Alpha Leonis
Rigel	Beta Orionis
Sirius	Alpha Canis Majoris
Spica	Alpha Virginis
Vega	Alpha Lyrae

Spectra of the Stars.—When the spectroscopic was invented and applied, one of the first uses made of it was to analyze the light coming from various stars in order to see in what respect they differed in their constitution. The result has been to show that, out of several thousand stars which have been examined in detail, it can hardly be said that any two are exactly alike. It is true, in the highest branch of science, that one star differeth from another star, not only in glory, but in the substance which makes it up, as well as in various other features. At the present time the spectra of the stars are best studied by means of photography. The general fact that lights can be photographed which are too faint to be visible to the eye is here applied with great success. When only eye methods were used, it was hardly possible to accurately define or measure the spectral lines given by any but the brightest stars, and even here the measures were so uncertain that few definite results were reached. But, by applying photography, the negative on which the spectrum is impressed can be placed under a measuring engine, and the settings made by means of a microscope with the highest degree of precision that admits of being reached.

At an early period of spectroscopic discovery, Secchi, the Roman astronomer, made an exact classification of the spectra of stars, which he connected with their respective colors. The bluish stars he designated as of the *first type*; those which were almost pure white or slightly yellowish were of the *second type*, while those approaching toward red were mostly of the *third type*. Speaking in a rough way, it would seem that these gradations correspond to the absorption of the light by atmospheres

surrounding all the stars. The more dense and the deeper this atmosphere the more blue light it absorbs, and the more red the remaining light appears. It seems, therefore, to be a general rule that the redder stars have the densest and most absorbing atmosphere. From many such stars a large part of the blue and green light is cut off. This deficiency in the blue light may also be due, in some cases, to the stars which show it being not so hot as the others; because we know that the hotter an object the more blue light it radiates in proportion to its red light. But everything we know of the stars leads us to believe that these cases are exceptional.

A very remarkable fact in connection with this classification is that the blue or first type largely predominates in the stars of the Milky Way, while stars distant from the Milky Way mostly belong to the other two types. Quite possibly it may be found that this distinction will enable us to determine in what part of the universe a star is situated, by means of its spectrum. When, at Harvard Observatory, the spectra of the stars were photographed on a large scale, and the number studied brought up into the thousands, it was found that Secchi's classification was quite insufficient. We now have a great number of such classes designated by letters of the alphabet and numerals which are too technical to be set forth in the present article. We shall mention but a single type known as Orion stars, because many of the stars showing it belong to the constellation Orion. A remarkable peculiarity of this type is the great number of fine lines in the spectra, many of which do not belong to any known substance. What gives great interest to it is that the stars which show it belong mostly or entirely to the Milky Way, and have markedly slower proper motions than the stars in general.

One result of spectral analysis is that most of the stars are composed in the main of the same chemical elements which we know to exist upon the earth: iron, calcium and hydrogen seem to be present throughout the whole universe of stars. It cannot yet be said with certainty to what extent elements unknown on the earth exist in the stars, for the reason that the spectrum of an element depends so much upon the conditions of pressure or temperature to which the substance is exposed. We may regard it as certain that, whether elements unknown to us do or do not exist in the stars, the substances which form the stars, and especially the nebulae, exist in many cases, in a form different from any we have yet produced in the laboratory.

Proper Motions of the Stars.—One of the most remarkable features of the universe is that every so-called fixed star is moving forward on an undeviating path which, so far as we can yet determine, is a straight line. This is called the *proper motion* of the star. Nothing is better calculated to give us an idea of the extent of the universe than the contrast between the speeds of these motions as we know that they really are and the apparent speeds as we observe them from the earth. The actual speed is enormous when compared with any that we can produce by artificial means. The speed of a shot from the most powerful gun that can be made can scarcely, if at all, exceed

half a mile per second. But if the motion of any star is as slow as one mile a second, it is only in very rare and extraordinary cases. The average speed of the stars is about 20 miles a second; and this motion, it must be remembered, is not, so far as yet determined, motion round and round in an orbit, but a straight-ahead motion, never relaxing and never swerving. Almost every star, therefore, travels hundreds of millions of miles every year, century after century. And yet, so slow do the motions appear to us that the naked eye can see no change in the configuration of the constellations during a period of thousands of years. A remarkable instance of this kind is afforded by Arcturus, which is, so far as we know, one of the swiftest moving stars in the heavens. It seems quite certain that its speed exceeds a hundred miles a second, and it may be much greater than this. And yet, if Job could again come to life and study the constellation Bootis, in which Arcturus is situated, he would scarcely notice any change in its appearance. There is not a star in the constellation Orion moving so fast that any change would be noticed by the naked eye in 100,000 years. The result is that the motions in question have been detected only by the most refined observations of modern times, extended through long periods. Every star in the heavens appears in the same position when observed night after night. There are very few in which the astronomer can detect any motion by one year of observations. Accurate determinations of position commenced with the observations of Bradley, Astronomer Royal of England, in the middle of the 18th century, who determined the position of more than 3,000 of the brighter stars. Since his time the position of several hundred thousand stars have been accurately fixed. Yet, so small is the apparent proper motion in most cases that it has actually been detected in the case of only a few thousand stars. Even now there are scarcely a hundred stars of which the motions are known to exceed one second in a year. To understand what this means we must reflect that it would take a good eye to see that two stars in the sky, 200 seconds apart, were not a single object.

The following is a list of the stars whose proper motions exceed four seconds in a century. In the first column is given the name by which the star is commonly known; in the second and third its position; in the fourth its magnitude, and in the last its proper motion in a year:

STAR	Position			Mag.	Prop. motion
	R.	A.	Dec.		
	h. m.		Deg.		Sec.
Cord. 32.416.....	0	0	-37.8	8.5	6.07
O Eridani.....	4	11	-7.8	4.5	4.05
Cord. Z. V. 243.....	5	8	-45.0	8.5	8.70
L. 21,185.....	10	58	+36.6	7.3	4.76
L. 27,258.....	11	0	+44.0	8.7	4.41
Groomb. 1830.....	11	47	+38.4	6.4	7.05
Barnard.....	17	53	+4.5	11.0	10.30
61 Cygni.....	21	2	+38.2	6.1	5.16
Bessel Indi.....	21	56	-57.2	4.8	4.68
Lacaille 9,352.....	22	59	-36.4	7.1	7.00

It is very remarkable that only three of these stars are visible to the naked eye, and

these three are below the fourth magnitude. It will be seen that the annual motion of the most rapidly moving star is less than 12 seconds annually. If this star were to continue its course round the sky without ever stopping, it would take it more than 105,000 years to make the circuit of the heavens.

Proper Motion of the Sun.—Our sun being one of the stars, we may expect that it also has its own proper motion. But this motion cannot be directly observed. The only way in which we can detect it is by the relative motion of the other stars, just as we know that a railway train is carrying us along when we see houses and trees seeming to pass by us. The motion of the sun was detected by observing that, notwithstanding the varied directions in which the stars appear to us to be moving, there is an average tendency to move from a point in the constellation Lyra toward the opposite region of the heavens south of Sirius. These two opposite points are near the Milky Way, though not in it. From this general community of motion we infer that our sun, carrying the earth and all the bodies of the solar system with it, is moving toward the constellation Lyra. The point toward which the motion is directed is called the *solar apex*. It was formerly supposed to be situated in the constellation Hercules, but more recent investigations have placed it farther to the east. Its position is still uncertain by several degrees, and there is some difference of opinion among astronomers as to its exact location. But the best results seem to show its position, as defined by right ascension and declination, to be about the following:

Right Ascension, 18 h. 30 m.
Declination, 35° north.

This point is about 4° south of the bright star Lyra. We may, therefore, say that our solar system is constantly journeying toward that region of the heavens where Lyra is situated.

Star Streaming.—The earlier determinations of the point of the heavens toward which our sun is moving were all based on the assumption that there are no widespread systematic motions among the stars themselves, that is, that when large numbers of them are considered any general backward drift of them all must be the effect solely of our own motion through space. If a considerable number of them are moving, or "streaming," together, the determination will be rendered inexact by this fact, although it is undoubtedly true that the direction and velocity of our motion as just described are very approximately correct. Several instances of star streaming have recently been discovered. Ludendorff has found that five of the bright stars of Ursa Major, though they appear to us widely separated in the sky, are moving together in parallel paths, and Hertzsprung has shown that the Dog Star, Sirius, though from our position it seems so far removed from the others, is also moving with them. The centre of this cluster is about 100 light years from us: Sirius, only 8.6 light years away, is thus far out of the centre.

An even more interesting example was discovered by Boss, who found that 39 stars, lying principally in the constellation Taurus, and

which appear scattered over a considerable area of the sky, do, in fact, form a globular cluster which is drifting through space with a velocity of about 25 miles a second. Some 800,000 years ago, this swarm passed nearest our earth, its centre then being 73 light years away. It is now about twice as far away from us as this and at the expiration of 65,000,000 years its 39 scattered bright stars will be so distant that they will appear to us as a faint, round cluster about two-thirds as large as the full moon.

A discovery of more widespread importance, however, is that of Kapteyn, who finds evidence of two very extensive systematic star drifts, the larger being directed toward the star Xi Orionis, and the other in an opposite direction. The cause of this extensive streaming is not known; it has been suggested that it may arise from a falling in toward the centre of the outer stars of the cloud which surrounds us, and which, therefore, may change its shape periodically through intervals of time so great that all other eras hitherto considered in astronomy shrink to nearly nothing in comparison.

Radial Motion of the Stars.—The most wonderful revelations of the spectroscope relate to the proper motions of the stars and lead to the measurement of the speed with which a star is moving to or from our system. This speed is called its *radial motion*. The possibility of determining it rests on the principle that the wave-length of light coming from a star is less when the star is approaching us and greater when the star is moving away from us. Hence, if, on measuring the refraction of a particular ray emitted by a star, we find it to be greater than its regular value, we know that the star is receding from us, and, in the contrary case, that it is approaching us.

It is very interesting that these measures agree as nearly as we could expect with observations on the position of the stars as to the direction in which our solar system is moving. Moreover, they have enabled Campbell to determine with an approximation to certainty the speed of the motion, which is about 11 miles per second. The whole solar system, and our earth with it, has, therefore, been pursuing a journey through space during the whole of human history, nay for hundreds of thousands, possibly for millions of years. Even with this rapid and continuous motion it will probably take us half a million of years to reach the region in which Vega, the brightest star in the constellation Lyra, is now situated.

The proper motions of the stars naturally suggest the idea that these objects all have their proper orbits and are performing revolutions round some centre as the planets do around the sun. The idea of a universe of which this might be true—of a system in which the years were counted by millions of our years is very captivating. But truth compels us to say that up to the present time astronomical science furnishes no sound basis for the reality of such a system: no resemblance of this sort can be traced. Moreover the general trend of science is toward the conclusion that the duration of the universe, though very long, is finite and is not sufficient to enable a star to have made many revolutions round any centre.

Double Stars.—A careful watcher of the heavens will notice that there are several pairs of stars in the heavens—two such objects being so close together as to suggest that they must have some connection. The most striking case of this sort is in the Hyades, a V-shaped figure having the bright red star Aldebaran at one end of the "V." In the middle of one of the lines of the "V" are two stars of the third or fourth magnitude, forming a very beautiful pair. This pair is easily to be seen in some part of the sky on any clear evening in autumn or winter. Another case of the same sort is that of one of the brightest stars in the constellation Capricornus, visible in summer and autumn, which has a much fainter star alongside of it. A third case is in the constellation Lyra, one of whose stars of the fourth magnitude can be seen by the naked eye to be composed of two separate stars. But only a very good eye can distinguish them from a single star.

When the heavens are scanned with a telescope, it is found that a great many stars which seem single to the eye really consist of two such objects in close proximity. Sometimes these are of the same brightness, but more commonly one is much brighter than the other. Very frequently the small companion is so faint and so close to the large one as to be lost in the glare of its light, except when very carefully examined by an experienced observer. Such pairs are called double stars.

The first question suggested by these objects is whether the two stars appear in such close proximity merely because they chance to be on the same straight line from us, or whether they are really in each other's neighborhood. The latter is known to be the case, for two reasons. In the first place these double stars are vastly more numerous than they would be if their proximity were merely accidental. Another conclusive proof is afforded by the fact that in many such cases the two stars are found to be revolving round each other, or the small one round the large one, as the case may be. The name *Binary System* is applied to such pairs. The most important and interesting conclusion drawn from the motions of these systems is that the law of gravitation extends to the stars. It is true that we could scarcely doubt such to be the case, even were no such proof available, but it is nevertheless of interest to have independent evidence of it. The revolution of the two stars round each other is in all respects similar to that of the earth and planets round the sun, or that of the moon round the earth. The time occupied in one revolution may be but a few decades, and in one instance it is but 5.7 years, yet in the vast majority of cases, hundreds or even thousands of years are required. As exact observations have only been made on these bodies since the time of Sir William Herschel, there are less than 100 of which the orbits and periods are accurately determined. Thus although the whole number known amounts to upward of 20,000 the determination of the orbits goes on very slowly.

There are two binary systems of special interest because the companion was first discovered through its attraction upon the larger star. One of these cases is the brightest star in the heavens, Sirius. About 1840 it was discovered by comparing observations made since the time

of Bradley (1750) that Sirius did not move forward on the celestial sphere with a uniform and even motion, as the other stars did, but that there was a slight irregularity. A few years later a careful investigation of the observations showed that Sirius was moving in a very small orbit with a period of about 50 years. This made it possible to calculate the orbit of an unseen companion which, moving round the star, would produce the apparent orbital motion. In 1860 Alvan Clark, the son and successor of the celebrated maker of telescopes in Cambridgeport, Mass., on pointing one of the newly made great instruments at Sirius, saw a companion star. He knew nothing about the computations that had been made on this object, but when his observations were compared with them, this companion was found to lie in the right direction to produce the observed inequality. The observations since made show that it is going round in the orbit prescribed for it before its discovery.

The other case is that of Procyon, the brightest star in the constellation Canis Minor. Its motion was found to be affected by an inequality somewhat smaller than that of Sirius; but the companion which produced it evaded the scrutiny of the most careful observers until it was discovered by Schaeberle with the great 36-inch telescope of the Lick Observatory. It also was found to be moving in the orbit computed for it before its discovery.

As the power of the telescope has been increased closer binary systems having shorter periods have been continually brought to light. This raises the question whether there may not be vast numbers of such systems in which the two stars are so close together that no telescope will separate them. This question has been answered in recent times by the aid of the spectroscope. We have already described how the radial motions of stars or the motion in the direction to or from our system is measured by this instrument. The determinations have been going on since 1880. As the number of measures increases, it is found that the radial motion of many of these stars varies in a regular period, thus showing that invisible planets are moving round them. A new feature of the universe is thus brought to our knowledge, which, if we had no other instrument than the telescope, would remain forever hidden. The difference between the measures made with the telescope and the spectroscope consists in this: The telescope can show the change in the position of a star only when it is great enough to be visible at the enormous distance of the star. Commonly this change must be measured by hundreds of millions of miles, nay, thousands of millions, else it would never be seen in the telescope. But the spectroscope shows, at any moment, how fast the star is moving to or from us, though it gives us no information as to its actual distance. It is not, therefore, necessary that the star should have moved through a definite space in order to have its motion detected by the change in its spectrum. Having given the speed of the revolution and the period, it becomes possible to determine the size of the orbit.

Pairs of stars discovered with the spectroscope are called *spectroscopic binary systems*. The comparisons in such systems are not, how-

ever, necessarily dark stars; the revolutions of a pair of stars, both of which are bright, may be determined with the spectroscope as if one of the bodies were dark. In this case the lines of the spectrum are sometimes double and sometimes single. They seem double when one star is moving from us and the other toward us, and single when the stars are moving laterally to the line of sight from us to them. Thus bright double stars are shown by the use of the spectroscope which no telescope, however powerful, can distinguish to be more than a single star.

That this doubling of the lines is a true indication of a double star system is shown by the fact that at least one spectroscopic pair can also be seen as a double in the telescope. The orbits derived from the visual measures and from a study of the light, respectively, are in remarkably close agreement.

The most successful discoveries in this line have been made in recent times by or under the direction of Professor Campbell, in the Lick Observatory, where it may almost be said that a new branch of astronomy has been created. The discoveries of these objects are now going on so rapidly that it is impossible to set any limit to their number. The general rule is found to be that the orbits described do not differ greatly in magnitude from those described by our planets in moving round the sun. That is to say, there are few or no orbits yet known which are as large as that of Neptune. There is, however, no limit to the minuteness of the orbits, some stars revolving almost in contact with each other.

Besides double stars, there are triple and quadruple stars of such variety that it is impossible to give any general description of them. The most remarkable quadruple system is found in the great nebula of Orion, where Theta Orionis, which looks to the naked eye like a single star, is shown by the telescope to consist of four stars forming a trapezium; this is, therefore, known as the trapezium of Orion. Altogether, these systems show the infinite variety of the great bodies which make up the universe. The pairs of stars which form a binary system may be of every degree of brightness and of very different masses. Their times of revolution range from two or three days to unknown thousands of years. In a few cases the masses have actually been determined. It is a curious fact that they do not vary so much as does the brightness of the stars. When a bright and a faint star form a binary system, the mass of the faint star is generally out of proportion to the amount of light it emits. We have already remarked that many stars are thousands of times as bright as the sun; but it is a curious fact that none have been found to have even hundreds of times the mass of the sun.

Variable Stars.—To ordinary observations, even to observations extending through generations, the light of the stars seem to be as permanent as the order of nature itself. But, although this is true of the great majority of stars which stud the heavens, it is now found that there are exceptions to the rule. So numerous have these exceptions become that the study of variable stars has developed into one of the important branches of astronomy. The

first star which was found to be variable in its light is known as Mira Ceti, or the wonder of the constellation Cetus, the Whale. This constellation extends from two hours to three hours of right ascension, and its central regions are situated a little south of the equator. It is on the meridian at some hour in the evenings of the winter months. The star Mira is quite invisible to the naked eye the greater part of the time, but is found to blaze up at regular but slightly varying intervals of about 11 months, sometimes attaining to the second magnitude. After remaining visible to the naked eye for a few days, it gradually fades away into invisibility, but may always be seen in a telescope. Its greatest brightness varies markedly. Sometimes it brightens up only to the fifth magnitude, and is then not at all conspicuous.

There are two other remarkable variable stars. One is Algol in the constellation Perseus, which may be seen in some part of the northern sky at some hour on almost any night of the year except in April and May. Commonly this star is between the second and third magnitude, and is usually classified as of the second magnitude. At regular intervals of a little less than three days, it fades away to the fourth magnitude, and then, after a few hours, gradually increases again to its regular brightness. It is now known that this diminution of light is a partial eclipse of the star; the brighter star is about 51 times as bright as our own sun, while the so-called "dark" companion is about three and one-third times as bright. Thus the companion is very far from being a dark body, but its interposition so greatly reduces the light which we receive from the brighter star that the effect of an eclipse is produced.

In another class of variable stars these two bodies are each of noticeable brightness so that the light which we receive from them varies twice in each revolution, once when the brighter star partially hides the fainter one, and once when it is itself partly hidden. Strictly speaking, the system of Algol should be now included in this class since by the employment of the delicate selenium photometer the light of its companion can be definitely measured.

The most remarkable of this class is Beta Lyræ, quite near the bright star Vega. It may be seen in some part of the northern sky during the spring, summer and autumn. Although the changes in its light are not striking, one who looks at it carefully night after night will notice them.

These three stars are only examples of a number of such objects now known to exceed 1,000, scattered over the whole sky. As observations become more and more accurate, it is found that quite a number of the stars visible to the naked eye are subject to slight fluctuations of light, mostly in a more or less regular period, but sometimes in a quite irregular way. Spectroscopic observations render it somewhat probable that in most cases the regular changes are produced by bright or dark bodies revolving round the star in very eccentric orbits. Sometimes they partially eclipse the star, as we have already mentioned; but in many other cases it seems likely that they make the star blaze up by the disturbance they make when they approach close to it in their orbits.

The general rule is that a variable star goes through its series of changes in a regular period. At a certain day and hour it reaches its least brightness, which is called a *minimum*. Then it begins to increase in light. In the course of a certain number of hours or days it increases to its greatest brightness; then it begins to decrease and once more fades away to its minimum. The length of time between two minima is a *period*. Commonly the successive periods of a variable star are nearly equal to each other, so that the stage of brightness at any future time can be predicted with confidence. The periods range very widely from a few hours to about 600 days. It is very remarkable that no period yet known exceeds two years. There are many periods less than a month; but there are only eight between 50 and 100 days. The number then increases up to 350 days. The greatest number of periods is just about one of our years, a coincidence which of course is a pure accident. Above this their frequency rapidly falls off. This limitation of the period strengthens the view that the variability of a great number of stars is produced by the disturbing action of an immense body revolving round the star in a very eccentric orbit.

New Stars.—In past generations, when the whole universe was supposed to be only a few thousand years old, it was quite natural to expect that new stars would from time to time be created to shine among their fellows. But this view has now to be modified. It is true that, from time to time, a star is seen to blaze out where none was known before. But the theory of a new creation is refuted by the fact that such stars invariably fade out in the course of a few weeks or months. On some very rare occasions they have continued visible to the naked eye for a year or more, and they can commonly be seen by the telescope for several years. The first remarkable case of this sort of which we have a scientific record occurred in 1752. On 11 November of that year, Tycho Brahe, the celebrated astronomer of Uraniburg, observed a star of the first magnitude in the constellation Cassiopeia. Before the end of the month it was so bright as to be visible in full daylight. Then it began to fade away and finally disappeared from view in May following. This was before the invention of the telescope, so that Tycho was unable to trace the star any longer. Thirty-two years later Kepler observed a similar star in the constellation Ophiuchus. This star continued visible to the naked eye for more than a year, but it never became so bright as the star of Tycho. As the heavens were more carefully watched, and photographs of the stars were taken, these new stars were found to be more frequent than was formerly supposed. During the 19th century 11 were observed to blaze out, more than half of which were during the last 14 years of the century. But the greatest number of them scarcely reached the limit of visibility to the naked eye, being discovered principally by photography. On 20 Feb. 1901 the most wonderful of these objects which had been seen for 300 years blazed out in the constellation Perseus. In two or three days it was the third brightest star in the heavens. Then, following the example of its predecessor, it gradually faded away, though it

still remains visible in the telescope. It is not yet certain whether this object was impressed on any photographs until within a few days of its first appearance.

Similarly on 8 June 1919 a brilliant new star appeared in Aquila, almost on the border between Aquila and Serpens. When brightest this was almost as bright as Vega, the brightest star of the northern heavens, and it was of a very blue color. It rapidly faded away, until now it is only a telescopic object.

By what convulsion of nature these objects burst forth it is quite beyond the power of our present science to decide. It is certain that the amount of light and heat emitted by these stars was suddenly increased hundreds or even thousands of times. One of the most plausible explanations is that of a collision. It is supposed that the star itself may have collided with another—perhaps a planet in its neighborhood—or rushed to its own destruction in some nebulous mass. But this is only conjecture.

Very curious has been the fate of these objects after they have faded away. Those recently observed have been found to change into nebulae; a mass of glowing gas emitting the bright spectral rays of hydrogen and other gases. Photographs and spectroscopic observations give evidence of some explosive action, throwing out corpuscles with immense velocity in every direction, but throw no light on the origin of the explosion.

Star Clusters.—One of the remarkable features of the heavens revealed by the telescope consists in star clusters—great numbers of these bodies crowded into a space which, measured by the expanse of the heavens, must be comparatively limited. It is not at all uncommon to find hundreds of stars in a single bunch so closely packed together that, to the naked eye or in a small telescope, nothing is seen but a minute patch of light. One of the most remarkable of these contains 60,000 stars, situated in the constellation Hercules, another in the constellation Centaurus was described by Sir John Herschel as one of the most remarkable objects in the heavens. There exists every variety of such clusters, from these closely packed ones to the agglomerations of the Milky Way, which any careful observer of the heavens can see on any clear evening during the late summer and autumn. Close together as the component stars of these clusters appear to be there is no doubt that they are really separate from each other by distances vaster than those which separate the planets of our solar system; otherwise the most powerful telescope would not distinguish them as separate stars, but present them to our view as if confused together in one mass of light.

By several different methods the distances from us of the globular clusters have very recently been found by Shapley of the Mount Wilson Solar Observatory. It is shown that while the cluster in Centaurus is the nearest, the more distant are not infinitely remote from our Milky Way cluster, but are outside of it and apparently connected with it. They are, in short, now known to be small universes of stars, the distances through them being measured in hundreds of light years instead of in

tens of thousands as in the case in our Milky Way cluster.

It is a remarkable fact that many of these clusters contain a great number of variable stars. This fact, taken in connection with the probable cause of variability already mentioned, makes plausible the idea that close binary systems are very numerous in the clusters. If, at any one moment, all the stars of the cluster were at rest, they would in course of time be drawn together by mutual gravitation. Each star must, therefore, be in motion relative to the others, describing some kind of an orbit around their centre of gravity.

The laws of revolution in cases like this must be very complicated, but as they require thousands of years to go through their changes and accurate observations have been made for hardly more than a century, astronomers are not yet able to investigate them fully.

Constitution of the Stars.—There is no reasonable doubt that the general constitution of the stars is the same as that of our sun; and that they consist of masses of intensely hot vapors of the substance composing them, compressed together by the mutual gravitation of their parts. As we have already said, the stars are composed in the main of the substances found to exist in the sun, but, probably, in a great variety of forms as regards density and temperature. The spectra of the stars, consisting, as most of them do, of a bright continuous spectrum crossed by dark lines, show that we see the luminous surface through an atmosphere cooler than itself, though really intensely hot.

The stars differ enormously in their actual luminosity, that is, in the actual amount of light emitted by each. If they were all equally luminous we could form an idea of their relative distance by their brightness; the farther a star was away the fainter it would shine. But as a matter of fact, some of the brightest stars in the heavens are so distant that their parallax proves to be immeasurably small. This is not the case with Sirius, the brightest of all, which has a parallax of $0''.38$, showing it to be situated at a distance from which light would travel in about nine years. But the next brightest, Canopus (not visible farther north than our Southern States), is so distant that no parallax can be shown by the most refined measures. The conclusion is that it must be 10,000 times as luminous as our sun; possibly 100,000 times. This is the case with several stars in or near the constellation Orion. At the other extreme, we find that among the nearer stars are several not visible to the naked eye. It is true that the nearest of all, Alpha Centauri, is nearly of the first magnitude; but the next in order, 61 Cygni, is only of the sixth magnitude; two others are quite invisible to the naked eye. This shows that there are stars much less luminous than the sun, and that the greatest stars are probably millions of times more luminous than the smallest ones.

SIMON NEWCOMB.

Revised by ERIC DOOLITTLE.

STARS AND BARS, The, a name applied to the flag of the Confederate States of America. It was an adaptation of the stars and stripes. On 5 March 1861 the Flag Committee appointed in the provisional Senate of the Southern States recommended that "the flag of the Confederate States shall consist of a red field with a white space extending horizontally through the centre, and equal in width to one-third the width of the flag." It was first displayed 4 March 1861, simultaneously with the inauguration of Lincoln, being unfurled over the State House at Montgomery, Ala. In 1863 the Confederate Senate adopted a white flag with one blue star in the centre, the Stars and Bars bearing too close a resemblance to the Stars and Stripes.

STARS AND STRIPES, The. See FLAG OF THE UNITED STATES.

STARVATION, or INANITION, lowered vitality, accompanied by emaciation, enfeeblement which if prolonged results in death, through lack of food. Starve is derived from Old English *steorfan*, to die. The phenomena of starvation presents subjects of great interest from their bearing upon phenomena induced through the inability to take nourishment occasioned by some diseases. According to Chossat, the symptoms which intervene in starvation are at first marked by a very rapid diminution in the weight of the body; this decrease, however, becoming more gradual as death approaches. A striking uniformity is found between the period at which death results from starvation and the loss of weight experienced. Thus Chossat found that in different warm-blooded animals death resulted when the body had lost about 40 per cent or two-fifths of its original and normal weight. Great variations undoubtedly existed in the extremes of Chossat's cases; the circumstances which seem most powerfully to have affected these results being the amount of fat contained in the body prior to the beginning of the starvation period. The animals which had

most fat stored up lost weight quickest and at the same time lived longest. Chossat found that in animals undergoing starvation the symptoms observed during the first half or two-thirds of the period are those of calmness and quietness; the temperature then becoming elevated, restlessness and agitation prevails; and when life is terminated by the rapid fall of the temperature stupor supervenes. The extremities become cold and weak, and are finally unable to support the weight of the body; while the pupils of the eyes become dilated; and occasionally at death convulsive twitchings may be present. The excreta are small in quantity after those which are voided as the result of the food last partaken of, and consist chiefly of greenish matters, probably derived from the biliary secretions. At death the faeces become watery and contain saline matters.

The fatty matters are almost entirely removed by starvation, and the blood loses three fourths of its original amount. It is probable that the total nutritive powers of the body during starvation go to nourish the nervous tissues, the loss of which is very small; while the true mode of death from starvation appears to be death from want of heat, the body being preserved alive, notwithstanding the want of fresh nutritive material, by the combustion or absorption of the fatty matters it contains. Chossat also found that proportionally to the more active nutrition and waste in young animals, such died sooner from starvation than older forms; and he also determined the equally important fact that if young animals especially are supplied with an insufficient amount of food, they succumb as if they were actually starved; the process of starvation being of necessity more gradual in the latter instance. The mere variations in the temperature observed by Chossat formed more prominent points of note in his observations than the actual decrease of heat. It fluctuated or varied daily, in some cases, some 5° and 6° F., instead of 1° and 2° F., as observed in the normal and healthy state of the body. In the human subject the symptoms of starvation have been closely studied by physiologists, with the effect of determining a stated order in their appearance and effects. The preliminary hunger appears to be accompanied in the first instance by severe pain in the stomach and epigastric region generally. The thirst becomes intense and although undoubtedly in man the want of water induces death at a much earlier period than where drink is attainable by lower forms (for example, birds), the want of water may in reality make comparatively little difference in the invasion of the fatal period. Sleeplessness appears to be early manifested; the severe pain at first felt in the stomach gradually ceasing. A characteristic feeling of sinking and weakness is described as occurring in the epigastric region, the thirst still continuing to an agonizing degree. The face assumes meanwhile an anxious, pale expression; the eyes are wild and staring; and the whole countenance and body participate in rapid general emaciation. The body latterly exhales a fetid odor; the breath and lung secretions become strong-smelling; and the skin is said to become covered with

a brown secretion—these results, doubtless, arising from the decomposition and organic decay of the tissues. The gait totters, the mind becomes impaired, delirium or convulsions may ensue and death occurs, with or without the accompaniment of diarrhœa. Post-mortem reveals a state of anæmia in all parts of the body but the brain, which appears to be the last to receive a due supply of blood. The fat is entirely wanting and the various organs and tissues have greatly lost in bulk. The coats of the small intestine are found exceedingly thin. The gall-bladder generally contains much bile, and the body goes more rapidly to decay than after death from ordinary causes.

Starvation suggests inquiries respecting abstinence in diet and from various or particular kinds of food. A sudden and unfavorable change in a given dietary may induce, in virtue of the new food containing a low percentage of certain nutritive matters, symptoms analogous to those of starvation. Want of nutriment produces an incapacity for the digestion of whatever amount is supplied, a result probably due to nervous causes and primarily perhaps to the want of stimulation of the appetite through insufficient secretion of gastric juice.

Where the temperature of the body is maintained in tolerable efficiency, life may be prolonged for great periods without food, a state of syncope prevailing—as in several noted cases of so-called apparent death. It was found by Chossat that in the case of animals whose death seemed imminent from starvation, restoration took place primarily by the application of artificial heat. They thus manifested activity, and were able afterward to partake of food. From 8 to 10 days is regarded as the usual period during which human life can be supported without food or drink. If water be given this period may be greatly exceeded, and where a moist condition of the atmosphere exists life may for the same reason be prolonged. A case is recorded in which some workmen were dug out alive after 14 days' confinement in a cold damp vault; and another is mentioned in which a miner was extricated alive after being shut up in a mine for 23 days, during the first 10 of which he subsisted on a little dirty water. He died, however, three days after his release. Life has been prolonged for 60 days in a person suffering from religious mania who abstained from food, supporting his existence by sucking an orange. In some remarkable cases of nervous hysteria and other diseased conditions no food may be taken and yet the body be perfectly sustained. The system is disposed or becomes inured to the abstinence, just as under other conditions it exhibits a want of susceptibility to the ordinary effects of certain medicines. (See FASTING). Consult Benedict, F. G., 'A Study of Prolonged Fasting' (Washington 1915); Davies, 'Starvation' (in *Popular Science Monthly* 1884-85, Vol. XXVI); Leeson, 'Death from Starvation' (in *Dublin Medical Press* 1847).

STARVED ROCK, a high, isolated pinnacle on the south side of the valley of Illinois between Utica and Ottawa, La Salle County, Ill. Its name indicates the fate of the last of the Illini Indians who were besieged by invading Iroquois Indians until their sup-

plies gave out. This rock, known as La Rocher to the French, was a famous locality all through the early history of the north-central Illinois region for it is a conspicuous landmark at the head of navigation in Illinois River. Late in 1682 La Salle built on its summit the fort "Saint Louis des Illinois" which was a most important outpost and intended to be the centre of a large French colony. With sheer walls rising 130 feet above the river at its northern base and almost inaccessible from the bluffs on its south side, it was easy to defend. The area on top was somewhat less than an acre. The fort was abandoned about 1690 and the Indians and traders finally left its vicinity. The rock consists of soft, massive, nearly horizontal sandstone of Saint Peters formation which constitutes the bluffy sides of Illinois Valley in La Salle County. It was isolated by erosion from the main body of the formation in the neighboring bluffs. It is claimed that the first bituminous coal used in the United States was obtained near Starved Rock about 1695. On account of its great historic interest and highly picturesque surroundings, Starved Rock has been made a State park of 10,000 acres. Consult Baldwin, C., 'History of La Salle County'; Carter, J. D., 'Last of the Illinois,' and Sauer, C. O., 'Geography of the Upper Illinois Valley' (State Geological Survey, Bulletin 27).

STASSFURTITE, a massive variety of the mineral boracite (q.v.) occurring chiefly at Stassfurt, Germany, where a few hundred tons are annually produced.

STATE. Political scientists of the present day distinguish sharply between the idea connoted by the term "state" and that indicated by the word "government." By "state" is meant the body-politic abstractly considered,—the entity that possesses and exercises the sovereign political will. By "government" is meant the mechanism of political rule, the ensemble of the agencies through which the tasks of the state are performed. The present article will be devoted to a discussion of the nature of the state. A treatment of GOVERNMENT will be found under that title.

As distinguished from a society, by which is meant simply an aggregate of human beings living together and united by mutual economic and social interests, a state is a body of individuals that has assumed an organized form, that has a definite membership, and has created for itself specific organs for expressing and enforcing its corporate will. Thus, in order that there may be a state, three elements must be present: (1) An aggregate of human beings, individually termed citizens or subjects, forming a single group and as such termed a "people"; (2) a political apparatus, termed a government, and administered by a corps of officials collectively termed a magistracy; and (3) a body of rules or maxims, written or unwritten, which are generally recognized to be such as may rightfully be enforced by those entrusted with the exercise of the powers of the state. Whether or not to these three essential elements there should be added a fourth, namely, a definite area of land, there is a difference of opinion. The eminent German publicist Bluntschli, who may be taken

as a representative of one view, defines a state as "the politically organized national person of a definite country." On the other hand, Holland declares that "a state is a numerous assemblage of human beings *generally* occupying a certain territory, among whom the will of the majority, or of an ascertainable class of persons, is, by the strength of such a majority or class, made to prevail against any number who oppose it." The definition of Bluntschli is undoubtedly applicable to all modern civilized states, but certainly is not descriptive of very many bodies-politic of the past. Indeed, political sovereignty, by which is meant the supreme power of the state, was for many years, according to the ideas of the peoples of western Europe, not territorial at all, but based upon a personal allegiance of the subjects to their rulers.

A people, a government and a body of laws are what may be termed the essential material elements of which a state is composed. In addition to these there is one characteristic that it must possess in order properly to deserve its title and to be distinguished from the others and lower types of political life. This unique and distinguishing characteristic is sovereignty. By sovereignty is meant the highest, or supreme power. It thus means that its possessor is itself the ultimate source of all the laws that are enforced over the territory which it claims as its own, and over citizens or other persons subject to its authority. It means, in short, formal legal omnipotence. The word formal is used, for of course the power of control that any state may actually exercise is limited by the intolerance of its subjects of oppression. But, formally, a state, because legally subject to the control of no other law-making power, has the power to issue such legally binding commands as it sees fit. Directly or indirectly, it is the source of all the rules that regulate not only the conduct of its subjects and others for the time being subject to its authority, but those that determine the form of its own government and the respective powers of its several organs and officials. The exercise of all political powers, either by individuals or associations of individuals, are, therefore, validated only by its sanction. The state is thus legally supreme, not only as the ultimate source of all law, but is itself the determinant of the matters that it will regulate, and the manner in which it will regulate them. Thus, as the Austrian publicist, Jellinek, has put it: "Obligation through its own will is the legal characteristic of the state."

It is the state, it is to be observed, that is the possessor of sovereignty—its "subject," as continental writers express it—not the government. To the government is entrusted only the execution of the sovereign will of the state. The powers of each governmental organ and of each public official are obtained from the state and are limited and defined by its laws. Thus at any given time a citizen, though potentially subject in every matter of life, liberty and property to the will of his state, possesses a sphere of freedom, defined by existing laws, upon which those exercising political authority may not trespass. To quote the words of Professor Burgess: "The individual is defended in this sphere against the government

by the power (the state) that makes and maintains and can destroy the government; and by that same power through the government, against encroachments from any other quarter. Against that power itself, however, he has no defense."

Sovereignty is an attribute of a political body that has to be demonstrated as a matter of fact, and not as a matter of law. In other words, there is no proper distinction between *de facto* and *de jure* states, these terms being applicable only to governments. (See GOVERNMENT). If a given community of human beings, yielding a general obedience to an established government, asserts and fairly demonstrates that it is able to maintain a freedom from the control of any other political power, it becomes by that very fact a state, and is entitled to recognition by other states as such. It is, however, the actual fact of independence from foreign control and maintenance of domestic order that demonstrates the existence of the sovereignty of the state in question, and not its recognition as a state by the other powers. Thus, for example, the American colonies ceased to be dependencies and became states not by reason of their recognition as such by England and European nations, but because of their actual ability to maintain that freedom from Great Britain's control which they formally asserted in 1776. The sovereignty of a state thus bears a double aspect. Considered internally, that is, from the viewpoint of municipal law, it appears as legal omnipotence. Looked at from the viewpoint of its relations to other states it appears simply as independence. In the one case, it means the affirmative legal power of enforcing its will upon all those subject to its authority. In the other case, it signifies simply freedom from foreign control. From the domestic standpoint, it signifies supremacy. From the international standpoint, it means equality.

The state, though itself the source of all law, can only operate through law. That is to say, an expression of its sovereign will can validly proceed only from those legislative mouthpieces that, by already existing law, have been granted the right to voice its commands, and these commands may be legally enforced only according to laws already established. Because of its legal omnipotence the state may at any time alter these rules according to the methods provided for the amendment or repeal of laws, but as they exist at any time the laws control. Any action not sanctioned by their provisions, however much approved by those in political authority, cannot, strictly speaking, be termed an action of the state.

Itself the creator of all law, the state is not itself a product of law. Constitutions create governments, not states. They are the creations of states already existent. The creative force, in the birth of states, is that feeling of unity interests and desires that leads a society of human beings to assume a corporate form and create the political organs necessary for the attainment of all those interests that are connected with or arise out of their existence as a national unit. This being so, it follows that sovereignty cannot arise out of any formal, legal or conventional act. In other words, a state cannot be created by formal agreement

between individuals, as postulated by the social compact theory, nor brought into being by a compact between sovereign states. By a surrender of private rights, individuals cannot create a public right; by a treaty agreement, there cannot be created a political power with a legal authority superior to that of the parties establishing it. From this last fact it irresistibly follows that any so-called composite or federal state that has for its basis a treaty or compact between states is not in truth a state at all, but a mere league of states, and this, notwithstanding the fact that very extensive powers may have been granted to the central governing power. Envisaged as a legal person, the sovereignty of a state represents the supremacy of its will. As thus representing a supreme will, sovereignty is necessarily an indivisible unity. A divided or double sovereignty is an impossibility. A given body-politic therefore either possesses sovereignty and is for that reason a state, or it has not sovereignty, and, as a result, is not a state but simply an administrative division of the state that possesses sovereignty over it. In all strictness then, it is a misuse of words to speak of a federal state, if by that term is meant a state formed by a federation of states; for if, in such a federation, sovereignty is held to rest in the central body, that body is a state, and its constituent commonwealth members are *ipso facto* reduced to a non-sovereign condition, and therefore to the status of administrative districts. If, however, the federating units each retain their sovereignty, they remain states, and no central sovereignty or state can be held to be created. In the one case, there exists but one state with a government composed of one set of central or federal organs and as many sets of local governmental organs as there are members of the union. In the other case, there exist as many states as there are confederated units, an equal number of state governments, and a central government that acts as the common agent of the several states; but no central state.

The line of distinction between a single national state composed of non-sovereign bodies-politic enjoying extended powers of self-government, and a confederation of states with a central government exercising many of the most important sovereign powers, is not always easy to draw. The distinguishing criterion is not the amount of powers actually vested in the central government as compared with those retained by the individual commonwealths, nor whether the operation of federal law is upon the individual states themselves or directly upon their citizens, nor, necessarily, upon the manner in which the articles of union may be amended. The one absolute test is as to the power or lack of power of the members of the union themselves to determine, in the last resort, not only the extent of the obligations imposed upon them by the articles of union, but their constitutional right to withdraw from the union when they see fit.

Bearing in mind the distinction between the possession of the sovereignty itself and the mere exercise of certain of its powers, it is seen that a state may, without in any wise impairing its sovereignty, delegate the execution of its commands not only to governmental agencies of

its own creation, but to those of other states; for, so long as such other states, or their governments, act but as the agents of the first state, it is the sovereign will of that state that is executed. And, furthermore, whatever may be its actual power, the state in question has the legal right itself to assume again the actual exercise of the powers it has granted. Such a withdrawal of delegated powers may be in violation of existing treaties, and, therefore, constitute a just ground for complaint, but it is not an illegal act, for treaties do not create law in the strict positive sense. Instances of the delegation by states to other states of the exercise of important powers is seen in the many so-called protectorates that exist at the present day. Confederacies, real and personal unions, and colonies are not similar examples, for in them the exercise of powers is granted to government organs created by the sovereign parties themselves.

Theoretically, there is no limit to the extent to which a state may go in the delegation to other states of the exercise of its power. If, however, in any one respect it is absolutely deprived of a power, so that it cannot legally, at its own discretion, resume the exercise of it, its legal omnipotence is destroyed and, together with it, its sovereignty and right to the title state.

Because the denial of the name state to non-sovereign powers makes it necessary to refuse that title to the many bodies-politic that generally have been, and are, so designated, as for example, the members of a federation such as the United States of America, many writers have endeavored to discover some distinctive attribute other than sovereignty that will serve sharply to distinguish states from provinces, departments and other simple administrative districts. The better opinion would seem to be, however, that these efforts have failed, and must continue to fail. With the test of sovereignty discarded, the dividing line between states and other political bodies becomes an indeterminate one, and, therefore, an exact definition of a state an impossibility. Logical exactness, therefore, even at the expense of wounding political sentiments, requires an adherence to the definition of a state as a necessarily sovereign body.

STATE COLLEGE OF WASHINGTON, The, located at Pullman, Wash. It was founded in 1890 in pursuance of the national land grant act of 1862 endowing agricultural and mechanical colleges. The national government granted 190,000 acres of land, the proceeds of the sale of which will constitute a permanent endowment for the institution. Women are admitted on equal terms with men. The regular courses are offered by the following colleges and schools: (1) College of Agriculture, which is composed of the following departments: Animal Husbandry, Agricultural Engineering, Dairy Husbandry, Farm Crops, Farm Management, Forestry, Horticulture, Plant Pathology, Poultry Husbandry, Soils. (2) School of Education. (3) College of Home Economics. (4) College of Mechanic Arts and Engineering, which is composed of the following departments: Architecture, Mathematics and Civil Engineering, Mechanical and Electrical Engineering, and Physics. (5) School of Mines. (6) School of Music and Applied Design. (7) School of Pharmacy. (8) College of Sciences and Arts, which is composed of the following departments: Botany, Chemistry, Chemical Engineering, Economic Science and History, English, Foreign Languages, Geology, Zoology. (9) College of Veterinary Science. (10) Department of Military Science and Tactics. (11) Department of Physical Education and Athletics.

In all the above departments the work in the four-year courses leads to the degrees of bachelor of arts or bachelor of sciences. The School of Pharmacy offers a two-year course leading to the degree of graduate in pharmacy (Ph.G.), and also a three-year course leading to the degree of pharmaceutical chemist (Ph.C.), in addition to the four-year course

which leads to the degree of bachelor of science in pharmacy. The College of Veterinary Science also confers the degree of doctor of veterinary medicine (D.V.M.).

The degree of master of arts (M.A.) or master of science (M.S.) is conferred upon the completion of one full year of work after receiving the bachelor's degree from this institution or another institution of well-recognized standing. Professional degrees in Engineering are conferred upon graduates of the State College who have been in successful professional work for at least three years and have had charge of difficult engineering or industrial enterprises.

There is also a Department of Elementary Science to which students are eligible after the completion of the eighth grade of the public schools. The courses offered in this department are largely along vocational lines in agriculture, commercial and mechanic arts.

The study of military science is required of all male students.

The college grounds include approximately 650 acres, 75 of which is set apart for the college campus. The buildings include the Administration Building, Bryan Hall, named in honor of Ex-President E. A. Bryan, Science Hall, Morrill Hall, Van Doren Hall, College Hall, Mechanic Arts Building, Mechanical Building, Veterinary buildings, James Wilson Hall, Music Conservatory, Ferry Hall, the dormitory for men, named for the first State governor of Washington, Stevens Hall, the dormitory for women, named for the first territorial governor, gymnasium and armory, College Hospital and the president's house.

The laboratories for instruction in the biological and physical sciences are well equipped with modern appliances. The library in 1917 contained more than 60,000 bound volumes and more than 100,000 unbound pamphlets and books. The students in 1917 numbered 2,130 and the faculty 225.

In addition to the colleges and schools mentioned above, in which courses leading to degrees are offered, the institution operates an agricultural experiment station in which the following departments are maintained: Agriculture, Botany, Chemistry, Dry Land Investigations, Entomology and Zoology, Horticulture, Irrigation Engineering, Veterinary Science and Plant Pathology. The experiment station is partly supported by funds established by acts of Congress. There is also a department of extension service operated in co-operation with the United States Department of Agriculture which is partly supported by the Smith-Lever fund established by Congress in May, 1914. The extension service consists largely in extension work in agriculture and home economics.

STATE CONSTITUTIONS. See CONVENTIONS, CONSTITUTIONAL IN THE UNITED STATES.

STATE CONTROL, Growth of. I. The State, an organized political entity, possessing and exercising sovereign powers, has always since its establishment controlled more or less completely the activities of its members, social, political, economic and moral, the extent of such control depending upon a number of factors, such as character of government, state of civilization, classes of society and political and

social ideals. States may be divided into two classes, according to whether government is completely centralized or not. In completely centralized governments, such as Great Britain, France and Italy, the right of control is entrusted to the national authorities while the local subdivisions such as counties and municipalities act as their agents. In the federalized form of government, such as the United States and Germany, the sovereign powers are parceled out between the national and local organizations, each government being independent of the other within its own especial field. With respect to growth, state control has exhibited two marked tendencies: first, that of the extension of the field of control entrusted to national authorities at the expense of the local subdivisions, and second, extension of control exercised by the government at the expense of the individual liberty of its citizens and members.

II. In general there are four distinct theories upon which the control of the state over individuals and groups of individuals is based, viz., the divine right of kings, *staatsgemacht* or force, the social contract, and social welfare. The first of these fundamental theories is aptly illustrated by the reign of Louis XIV of France and his slogan, "l'état c'est moi." During the past generation the theory was expounded and practised by the former emperor of Germany, Kaiser Wilhelm II, with what results the world knows too well. The second theoretical basis, *staatsgemacht* or the doctrine of force, is in practice, although not in theory, closely associated with the first, for the purpose of giving a religious sanction to the dominating influence of the state over its citizens. The third theory, that of the social contract, first formulated by Jean Jacques Rousseau in his brilliant but now generally discredited 'Social Contract,' constituted a distinct advance in political thinking and was naturally accompanied by marked improvement in national administration and in social wellbeing. The fourth theory, that of social welfare, was first enunciated by Aristotle in his 'Politics' and revived by the publicists and statesmen of England and continental Europe during the course of the 17th, 18th and 19th centuries. As an evolutionary institution, the state is held to be the natural development of the family and like it exists not for its own ends but for the benefit of its individual members. According to this theory, the state should exercise control over its members whenever and wherever such control results in the general welfare. To determine the scope and extent within which state control may be wisely exercised for the good of its citizens, representative governments have become a practical necessity.

III. During the Middle Ages and even well into the period generally denominated modern times, all the more important European nations were either absolute or limited monarchies and their governments were dominated by a group of courtiers who professedly believed in the divine right of the kings under whom they served. As the rank and file of the citizens grew in political wisdom they began to discuss the functions of government and the proper limitations of public control over private rights. The first great movement along these lines began in England in the early part of the 17th

century and culminated in the overthrow of the Stuarts and the establishment of the Puritan Commonwealth in 1649. Unfortunately for the progress of civil liberty the Commonwealth proved unequal to the task imposed upon it, and it was not until the revolution of 1688 that the foundations of parliamentary government and its concomitant, a decent regard for the rights of individual men, were securely laid. From this date onward in England and the English-speaking countries the evolutionary theory of government gradually grew to be the predominating one, and with its growth the policy of economic liberalism became firmly established. As a result of the forces set loose by the American and French revolutions, despite the brief militarism of Napoleon and of the reactionary movement led by Metternich and supported by the Holy Alliance, the century beginning with the year 1776 may be characterized as the Golden Age of political and civil liberty in every domain of life. During this period mercantilism as a national policy was overthrown, the old time restrictions on trade and industry were largely abrogated, and men were more nearly free to seek their own fortunes and to live their own lives without interference by the government than ever before in the history of the civilized world.

IV. The establishment of civil and economic liberty even within the limitations set by the more progressive governments, notably those of the United States, Great Britain and France, brought results not wholly favorable to the welfare of certain classes of individuals. While the world grew rich with unprecedented rapidity, the wealth tended to accumulate in the hands of a somewhat limited few.* The rank and file, although living in comparative affluence compared with their former status, still remained poor. In the defense of the new system a great literature was created, among which Adam Smith's 'Wealth of Nations,' John Stuart Mill's 'Political Economy,' Herbert Spencer's 'Social Statics' and the 'Man versus the State,' and Bastiat's 'Harmonies Economiques,' should be especially mentioned. Notwithstanding the intellectual triumphs achieved by each of these able defenders of the new order, abundantly supported by hosts of lesser lights, the accumulative unfortunate effects of excessive economic freedom became too pronounced to be longer ignored by the various states and, therefore, beginning about 1830, the tide began to turn in favor of larger state control. To relieve the situation without at the same time changing the established order became the chief object of the political leaders in England, France, Germany and the United States. Palliative measures, such as the English Poor Law of 1834, centralizing and standardizing the administrations of charity, abolishing out-of-door relief for the able-bodied, reinstituting the workhouse test, regulating the length of hours and the conditions of employment for child labor, were concomitantly tried. Such measures, however, were largely ineffectual because they failed to strike at the root of the trouble, and naturally enough, attention was more and more directed toward a study of the causes which were producing the

* King, 'The Wealth and Income of the United States' (New York 1913).

unfortunate and unsatisfactory results. As the investigation progressed the students of the social order almost immediately separated into two classes: first, those who deemed it wisest to destroy the existing system and inaugurate an entirely new one; second, those who proposed to preserve the fundamentals while eliminating certain non-essential features which had been found to be injurious to the common welfare.

The first group of reformers almost immediately divided into two branches, the Owenites and the Marxians. The Owenites, followers of Robert Owen, established a large number of independent communistic societies, the most of which soon disappeared and the Owenites with them, although their ideals are still of large influence. The Marxians, on the other hand, although since 1848 continuously exercising large influence on political and economic theory, have never until the present war, except in a very small way, had an opportunity to give their solution a practical trial. With the downfall of the Russian Revolution and the subsequent creation of the Bolshevik government, they have established a laboratory for the practical test of their ideals. If this experiment in industrial and social reorganization should prove able to produce goods as abundantly and at the same time distribute them more fairly than the capitalistic system, the latter will for the first time in history have encountered a real competitor. The adherents of the present system will in the latter event be under a stronger pressure than ever before to institute a sufficient amount of governmental control to insure that the products jointly produced shall be fairly distributed among the factors of production.

The second group of reformers, while attempting to maintain the competitive capitalistic system for the sake of its great efficiency in production, have at the same time desired to introduce a sufficient amount of state control to secure what they considered a high degree of fairness in distribution. Their efforts have been centred upon certain critical problems of which the following are the more important:

(1) Protecting wage-earners (a) against unfavorable conditions of work and (b) against inadequate wages.

(2) Protecting consumers by (a) preventing the establishment of industrial monopolies; (b) by maintaining free competition among business enterprises, and (c) maintaining standards in the character of the goods which are produced and sold.

(3) Creating systems of taxation which, while providing abundant revenue for the uses of the government in undertaking and maintaining state control, will at the same time act as an adjusting force in the distribution of wealth.

1. (a) It was early pointed out* that while the laborer was legally free to work for whom he pleased and could refuse employment where conditions or wages were unfavorable to him, the employer could generally wait until the terms he offered were acceptable, while the laborer generally could not; that, while the employing classes were living on their capital the employees were starving; that consequently

the state ought to interfere on behalf of the laborer, prescribing by law the conditions under which the work might be carried on, and in certain cases at least the wages at which the laborers might work. It was further noticed that the economic independence of the laborer was largely conditioned by the character of the industrial organization, and that wherever machinery was largely employed the relative advantage of the employer was increased. On this account regulation in behalf of the laborer began earlier in the machine trades and in those countries where machine production was most widely used. England, being the first to introduce factory production on a large scale, naturally encountered the labor problem first, and it is there that the foundations of the present system of state control in the interests of labor were laid.† In the United States the labor problem attracted little attention until after the Civil War. In 1869 Massachusetts created the first labor bureau‡ in the world, and following her example a large number of the States in the American commonwealth have established similar departments, manned by a considerable force of inspectors and administering laws which are intended to protect the laboring classes from work under conditions unfavorable to either health or morals. In the case of certain classes of labor the maximum number of hours which the laborer may work has been prescribed by law. As a result of state control in this sphere of action it has come to pass that the conditions under which the American laborer works are fairly conducive to good health, to a reasonable standard of morals and to a fairly long life.

The general establishment of the factory system, together with its necessary concomitants, mining and railway transportation, introduced a new element into the labor problem, mainly that of danger to life and limb. Until comparatively recent years it was generally assumed by those responsible for legislation that the wage-earning classes were fully capable of taking care of themselves; that placing the risk of the industry upon the employers would be sure to result in carelessness on the part of the operatives and high cost of production for the goods sold. It was, therefore, the established rule of law in all countries that the employer would be held responsible only for damages to life and limb due to his own negligence, while the employees must suffer those resulting from their own lack of care. To secure redress for injuries due to the carelessness of the employer the employee was obliged to bring a suit at law, stating the cause for his complaint and offering evidence to show that the employer was legally responsible for the accident that caused the damage. In the litigation that arose over such cases the judges in the absence of specific statutes to the contrary developed a series of common-law doctrines which to a large extent modified the original theory of the law. These doctrines are: that of contributory negligence, of assumption of risk, and the fellow-servant rule. Under the common law the employer could be held liable only when the accident was due to his own fault or neglect, but not when the negligence of the em-

* Owen, "Observation on the effect of Manufacturing System, etc."

† 3 & 4 Wm. IV. c. 103. 16 & 17 Victoria, c. 54.

‡ 3 Dec. 1913 there were 42 such bureaux.

ployee contributed to the accident or when the accident was due to a natural risk of the employment, nor when the accident was due to the act of a fellow-servant. Under these conditions the employer was legally responsible for damage resulting from certain classes of accidents; but even when legally responsible it was not easy for the injured employee to prove his case and collect compensation for the damages. Moreover suits against the employer were not conducive to pleasant relationships and gradually it became the custom for the employer to take out liability insurance under which the insurance companies undertook to defend all suits as well as to pay all damages incurred. Thus, while the liability to pay damages on account of accidents was a real factor in the cost of production, viewed from the employers' standpoint, comparatively little of this expense filtered into the pockets of the employees as compensation for their injuries. With the growing appreciation of the unfairness of the common law, the social reformers of the revolutionary type proposed and finally secured remedial legislation by the passage of the so-called workmen's compensation acts, by virtue of which the common-law rules were largely and in some cases fully abrogated, and in their place a system of direct compensation for various accidents substituted. In this movement Germany took the lead, establishing the first system of accident compensation on a large scale in 1884.* Since that date 48 other countries, including the United States, have adopted the same national system, and in the United States 35 of her Commonwealths and Territories had, on or before the first of January 1917, enacted either compulsory or elective compensation acts. In general, the administration of the compensation acts is entrusted to a commission, that established in Wisconsin in 1911 being generally regarded as an efficient type.

1. (b) State control of wages has for reasons that are readily appreciated made much less progress than public regulation of the conditions under which the laborer works. The movement of establishing public control of wages began in New Zealand in 1894, and for 15 years thereafter was confined to the countries in that corner of the globe. Since 1909, when the first minimum wage act in any of the older countries was passed by the enactment of the Trade Boards Act of October 1909, in Great Britain, the system has been extended in that country to coal mines by the act of 29 March 1912, and in the United States to various lines of work in certain of the commonwealths. The arguments relied upon to defend the system of minimum wages are similar in their nature and in their validity to those advanced in favor of the compensation acts, namely, the failure of competitive forces to insure a fair distribution of wealth for those engaged in certain occupations. While no method has yet been devised by which a reasonable wage may be determined by law it has not proven impracticable to establish minimum wages in the sweated industries on the basis of wages for similar work in the non-sweated industries. The object and the natural results of minimum wage legislation then is found to

be the restoration of normal competitive conditions by state action in those industries where the *laissez-faire* system has for reasons that are sometimes obscure, but more often patent, failed to work.

2. (a) From the age of Elizabeth, when the English patents of monopoly threatened to become a prominent feature of the Crown's prerogative, up to the period of the Civil War in the United States, competition between industrial and commercial enterprises was sufficiently active and at the same time sufficiently moderate to prevent the growth and development of industrial monopolies in a large way. Immediately after the conclusion of the Civil War conditions began to change, the new conditions tending to promote the growth of large combinations and consolidations in various fields of industrial activity. The first of these conditions was economic, the second moral and intellectual. With the development of steam as a motive force, the larger factories were found to be more efficient as producers of standardized commodities, and a process of elimination thereupon followed, the smaller factories giving way to the larger ones. At the same time the proprietors and managers formerly abnormally hostile and suspicious began to get acquainted with each other at the clubs and at informal gatherings, and as a result of this acquaintance they discovered that, contrary to their former beliefs, co-operation was oftentimes more advantageous than open and continuous warfare. As a result of these two concurrent forces the consolidation movement began first among the railroads and later among the industries. The railroads began consolidating even before the Civil War, while the first of the great industrial consolidations began with the union of the interests of the Rockefellers, Andrews, Harkness and Flagler, in 1867. From that date until 1904, when the government became active in controlling the formation and operation of various kinds of combinations, the consolidation movement was uninterrupted in its progress when measured either by the number of enterprises united or by the size of the resulting organizations. The trust movement began to attract public interest in certain sections of the country as early as 1877, although it was not until 10 years later that the problem became a national one. As a result of the investigations made by Congress in connection with the preparation and enactment of the Interstate Commerce Act of 1887, public attention became more intensely focused upon consolidations, their nature and import, and after two years of discussion the Sherman Act of 1890 was enacted into law. During the same period the State legislators were engaged in investigating combinations and in passing certain acts to protect intrastate business from monopolistic enterprises, so that by the end of the 19th century 32 of the American States had anti-trust acts on their statute books. Notwithstanding the legislation prohibiting such organizations, the trusts continued to develop, and it was not until the creation of the Bureau of Corporations, 14 Feb. 1903, and the simultaneous adoption of a vigorous administrative policy by the Department of Justice, that the trust movement began to abate. Since 1903 a considerable number of combinations have been

* Workmen's Compensation Laws of the United States and Foreign Countries. Washington, D. C., Bureau of Labor Statistics.

dissolved, several of the corporate consolidations have been disintegrated and at the same time the formation of new combinations and new consolidations has generally ceased. When America entered the World War, suits then in progress, directed against several of the larger consolidations, were by action of the Supreme Court, on motion of the Attorney-General, postponed for the duration of the war. It may be inferred, as a result of the better knowledge of co-operative effort engendered during the World War, that the policy of the administration and of the courts will be affected in such a way that decisions like that rendered in the Northern Securities case of 1904 will no longer be possible. On the other hand, combinations will be judged from the efficiency standpoint and government control established in such a way that their efficiency may redound to the common good.

2. (b) In 1914 an important change in the laws relating to combinations and competitive methods of doing business was introduced by the repeal of the act creating the Bureau of Corporations, and the enactment of two additional statutes for the better regulation of the activities of business enterprises. The first of the two acts was that creating the Federal Trade Commission*; the second, the Clayton Act.† The result of the legislation of 1914 was to establish a commission of five persons in place of the Bureau of Corporations and to impose upon the newly-created commission certain additional duties, of which the most important are: the enforcement of fair methods of competition‡ and the establishment of certain standards by which fair competition may be judged. During the year ending 30 June 1918, the Commission received 332 complaints charging unfair competitive methods or other violation of the acts under which they were operating. Since the creation of the Federal Trade Commission much more attention has been given to maintaining fair competition among competing business enterprises and less to the investigation of the combinations of various kinds. If, as confidently believed by many students of industrial conditions, the establishment and maintenance of fair competitive conditions by government action is efficacious in preventing many types of combinations, then the problem of industrial monopoly for the immediate future is partially if not completely solved.

3. While the state has always either directly or indirectly exercised its sovereign right of taxation for the purpose of providing revenue to meet its expenses, it was not until recent years that tax systems were designed with the avowed purpose of controlling the production and the distribution of wealth. Taxes for the purpose of controlling production, either directly or indirectly, are illustrated by those on beverages, narcotics and certain drugs. Sometimes the article itself is taxed, sometimes the privilege of selling, as license fees for saloons and other articles whose consumption it is desired to check. Another example of ancient lineage is the tax on importation or exportation. In

this case production is checked in one country and promoted in the other, the ultimate effect of the tax being determined by the rate of the tax and by the elasticity of the demand. The international economic effects of State control through import duties is aptly illustrated by the historical evolution of Great Britain and Germany. The former nation has followed the policy of *laissez-faire* with respect to foreign trade, the latter that of public control through the tariff. Great Britain became a specialist in manufacture with a consequent large development of international commerce. Germany became an all-around producer, a farmer, a manufacturer, a trader and a financier, good in each without being pre-eminent in any. When the World War came on, England's most vulnerable spot was her dependence on foreign trade for food as well as for a portion of her raw materials, and Germany, well knowing this, launched her submarine campaign as her best line of attack. To parry this offensive, England was obliged to maintain at her peril her acknowledged mastery of the seas in order that her merchant marine might bring the requirements which her position as a specialist daily demanded. Germany on the other hand was able to withdraw from the seas since her diversified powers of production were sufficiently extensive to provide for her major wants for a considerable period of time. In view of the experience of England and Germany some publicists have argued that taxation through tariffs ought to be more widely used for the purpose of forcing a nation to become more largely self-sufficient in the production of the essentials of a complete national life.

Taxation for the purpose of controlling the distribution of wealth has long been understood by economists and statesmen but, for reasons that are patent, little used until the recent World War furnished the necessary stimulus by imposing burdens upon the participating governments so stupendous that the historic methods of raising revenue were found to be entirely inadequate. To find additional revenue without at the same time imposing burdens of crushing weight upon the poorer classes of society, rates of taxation, it was thought, must progressively increase with the size of the income. As a result of the war, then, we have a new system of taxation in actual operation, one whose ultimate effect is to change profoundly the distribution of wealth by relieving certain of the poorer classes largely if not entirely from the paying of taxes based upon incomes and imposing far weightier burdens than ever before upon those whose incomes exceed the requirements of rational life.

V. War, by emphasizing the importance of concerted action, strengthens the hands of those who believe in an efficient and extensive system of state control, and at the same time and for the same reason weakens the cause of those who favor the policy of economic liberalism. On this account the period beginning with the Civil War of 1861 and terminating with the Franco-Prussian War of 10 years later marks a turning point in the growth of state control. It was generally conceded that the Prussian system was efficient and the results of the three wars by means of which Prussia became the dominant force in central Europe argued so eloquently for strongly centralized governments

* Act of 26 Sept. 1914, 38 Stat. 717.

‡ Consult Stevens, *Political Science Quarterly*, June 1914, p. 283 et seq.

acting under wide powers that even England and the United States began to study, to admire and then to copy the style of government which they had previous to this period condemned in theory* and avoided in practice.† But even though yielding somewhat to the adherents of the Prussian system the rank and file of the English and American people resisted the proposed innovations, and when the World War came in August 1914, both nations, Great Britain and the United States, were still predominantly exponents of a modified *laissez-faire* system. Germany on the other hand, partly as a result of certain habits and traditions and partly because of the fact that she was always either engaged in, or preparing for war, continued to extend the activities of her government so widely and so deeply that no private interest and no individual was left untouched. By this process of prussianization, individuals instead of being left free, either partially or wholly, to pursue their own courses as it seemed best for their own interests, were forced to shape their activities in accordance with the policies determined upon by the government of the day. Industries that were thought to be essential for success in war were fostered and protected by subsidies or other favoring legislation. Economic and social institutions were encouraged and established or discouraged and prohibited according as they were thought to be elements of national strength or causes of national weakness. The general results of this policy became evident immediately the World War was well under way. England and the United States, strong in peace, were weak in war. France, a nation historically opposed to extensive state control, had so far copied the Prussian system as to maintain a formidable standing army while otherwise following the policy of England and the United States. France therefore was able to hold the German forces in check while England and the United States, the pronounced exponents of economic liberalism, began to prepare, the former because she became a participant at the outset, the latter because it early became evident that she might be involved at any instant. Both England and the United States thus found it necessary in the interests of national efficiency to abandon their historic methods of managing their domestic affairs and substitute therefor the one by which Germany had so completely unified her national resources, men and materials, labor and capital, and turned the machine thus created upon those who threatened to block her path in her quest for world empire.

To accomplish the transition from a *laissez-faire* government to a system of complete State control, England, France and the United States followed similar paths. To secure adequate transportation facilities for the national needs it was early perceived, especially in England, that the railway, shipping, telegraph and telephone, all these instruments of communication, must be operated as units under the direct control of the central governments and with small delay the required authority was granted the several administrations. Communication through railways, ships, telegraphs and telephone is, however, only an instrument of production, and production of arms, of food and of clothing, in

the necessary quantities and of the proper kinds were equally essential to the successful prosecution of the war. Factories that had been producing non-essentials must be made to produce essentials and farms and mines must join the factories in furnishing raw materials, food, minerals and other necessary articles for an efficient life. To secure control over production, factories and mines were commandeered, enlarged or closed down as the situation demanded. Having secured control of production and communication, a third step became natural in all cases and necessary in some, that of control over distribution by means of which material and labor available for use could be divided among men and industries in such a way that each unit of productive power would be most useful to the nation without regard to any other factors. In carrying this policy of completely unified state control into operation, the United States adopted a somewhat different plan from that followed in England. Whereas in the latter country authority was largely centred in the ministry of munitions, in the former it was divided up among a considerable number of administrative organs, partially independent although in general centralized under the immediate control of the President. Thus where England had her ministry of munitions, the United States had the food and fuel administrations, the emergency fleet corporation, the war trade board, the war industries board, the federal railway administration, the national war labor board, the labor policies board, and the United States employment service, all acting as separate entities except as unified by the common control exercised by the chief executive. By such means, the industrial activities of all classes of citizens in the allied countries were soon after the beginning of the war as completely and it is probable, as efficiently controlled as in that great prototype of state control, Germany herself.

Now that the war is over and peace has come again the question as to whether economic liberalism has been abandoned permanently or only temporarily is the most important one now before the western world. The ease and facility with which the allied nations transformed themselves into fighting machines, the initiative and resourcefulness displayed by industrial leaders and working men in conducting to a successful conclusion a war for which they had not directly prepared, furnishes strong if not conclusive evidence that the economic system under which they have been living and prospering in the past possesses merits of such a character that it should not be lightly discarded in favor of one that has been proven to be provocative of wars and destructive of individual initiative and individual character.

STATE DEPARTMENT, one of the 10 executive departments of the United States government. It is presided over by the Secretary of State (q.v.), who is a member of the Cabinet, and next in line to the Vice-President for the Presidency. The department was established by act of Congress, 27 July 1789.

* Pollock, 'History of the Science of Politics.'

† Dicey, 'The English Constitution.'

Through this department communication is made between the United States government and any of the States or any foreign country. The department has charge of the great seal of the United States; of all ambassadors and consuls, and in its custody are all engrossed copies of the laws of the United States and of all treaties. The Secretary of State publishes all statutes and resolutions of Congress and all proclamations of the President of the United States. Under his charge, too, are all passports issued to American citizens visiting foreign countries; and all warrants for the extradition of criminals for delivery to foreign governments. It is the duty of the Secretary of State to make a report of the activities of his department annually as to its conduct of the foreign relations of the United States. There are three assistant secretaries in the department and a large force of clerks, translators, librarians and other employees. Bigelow, John, *'Breaches of Anglo-American Treaties'* (New York 1917); Butler, C. H., *'The Treaty-making Power of the United States'* (New York 1902); Corwin, H., *'The President's Control of Foreign Relations'* (Princeton 1917); Foster, J. STATE EXECUTIVE. See **EXECUTIVE.**

STATE FORESTRY. See **FORESTRY IN THE UNITED STATES.**

STATE GOVERNMENT, American. "The States," said Lincoln, "have their status in the Union and they have no other legal status." The powers reserved to the States, their obligations to one another and to the Union, and the obligations of the Union to them: all are provided for in the Constitution of the United States. The people of the United States under their National Constitution have assumed the obligation of guaranteeing to each State the republican form of government, of protecting it against foreign invasion and domestic insurrection and of securing to its citizens all the rights and privileges of citizens of the United States. Each State, on the other hand, is obliged to respect the supremacy of the Constitution, the laws and the treaties of the United States and to permit its government to act for certain purposes as the agent of the government of the United States. In general, however, the government of the United States operates directly upon the people of the United States and there is no occasion to rely upon the State governments for the accomplishment of national purposes. The States are also obliged to give full faith and credit to one another's public acts and records, to extend equal privileges to one another's citizens, to return fugitives from justice and to submit controversies among themselves, if not settled by mutual agreement, to the arbitrament of the Supreme Court of the United States. The power of the national government, however, to enforce some of these obligations is defective,

Powers of the States.—The powers reserved to the States may be said in a general way to include all the powers of free and independent States, except: (1) those which are expressly delegated to the government of the United States or are reasonably implied in the grant of the expressed powers; (2) those which are expressly prohibited to the States; and (3) those which, though neither expressly delegated to the national government by the Constitution nor prohibited by it to the States, are reserved to the people of the United States. Of the powers expressly delegated to the national government some, such as the power to govern the territories of the United States or the District of Columbia, do not directly affect the powers of the States. Some of those, however, which do not directly affect the powers of the States, such as the powers to tax, to regulate interstate and foreign commerce, and to make treaties, may be used in such a manner as indirectly to affect very strongly the exercise by the States of their reserved powers. Others, such as the power to establish a uniform bankruptcy law, may not limit the powers of the States unless Congress expressly so orders. Some powers, such as the power to coin money, are re-enforced by express prohibitions upon the States. The other express prohibitions upon the States are of varying importance. Probably the most important, besides those intended to give the national government exclusive control of foreign relations and the conduct of war, are those incorporated in the Constitution at the close of the Civil War, notably the provision that no State shall deprive any person of life, liberty or property without due process of law nor deny to any person the equal protection of the laws. Finally, the reservation of certain rights to the people of the United States by the 10th amendment, adopted in 1790, prevents the States from exercising any powers which, though not expressly delegated to the national government nor prohibited to the States, are essential to the preservation of the sovereignty of the Union.

The people of the several States are subject to the sovereignty of the people of the Union, but the people of each State are equal to those of any other before the law of the Constitution. Congress may admit new States to the Union, imposing such conditions as it may deem suitable as the price of admission, but once within the sacred edifice a new State becomes the peer of the others. The powers which the States may exercise, though limited, are nevertheless very extensive and highly important. They include among others the following: (1) the power to establish and maintain organized governments, State and local, subject to the limitation that they be republican in form; (2) the power to regulate the suffrage, both in State and in national elections, subject to the limitation that no citizen be deprived of the vote on account of race, color or previous condition of servitude; (3) the power to levy and collect taxes, except upon the instruments of the national government and upon interstate and foreign commerce; (4) the police power, including the power to enact all measures restricting the personal freedom of the individual or his use of his property,

which may be necessary and proper for the preservation of the peace, the protection of the public health and morals or in any other way for the promotion of the common welfare, subject to the limitation that no person be deprived of life, liberty or property without due process of law or denied the equal protection of the laws; (5) far-reaching powers to deal with education, religion and the supply of public services of all kinds, except the comparatively few, such as the post office, which are placed in the hands of the national government; (6) the power to create corporations and trusts; and (7) to deal with the whole subject of private law, including the power to regulate the vital institutions of modern civilization, such as the family and the institution of private property. Despite the growing centralization of government in the United States, evidenced by the adoption of the 18th Amendment to the Federal Constitution, the so-called prohibition amendment, the powers of the State remain, as they were in the beginning, more important than those of the Union, so far as concerns the regulation of the daily life of the people.

Rights of the States.—The basis of the State is the Constitution of the United States, but the basis of State government is the State constitution. The original State constitutions, adopted at the time of the Revolution, contained (1) an enacting clause, (2) a frame of government, (3) a schedule, and (4) in most cases a declaration of rights. In some cases there was also a preamble, setting forth the reasons for the adoption of a State constitution and intended to justify the overthrow of the former government. The declaration of rights ordinarily comprised a statement of the political philosophy of the Revolution and of the civil rights claimed for the people. The political philosophy was not radically different from that set forth nearly a hundred years earlier by John Locke in justification of the English Revolution of 1688. The civil rights were of two kinds: (1) abstract rights, such as the right to freedom of speech and of the press; and (2) concrete rights, such as the right to the writ of *habeas corpus* and to trial by jury. Practically it was upon the latter kind of rights that the former were dependent for their force. The declarations of abstract rights, to be sure, had their effect upon public opinion and thereby indirectly upon the conduct of government, but the system of trial by jury enabled the people to impose a direct check upon the acts of those in authority. The schedule dealt with such matters as the boundaries of the State and the transition from the provisional to the constitutional government. The frame of government was a body of rules for the organization of the government and the division of powers between its several branches. It also regulated to some extent the conduct of elections and the procedure of the legislative, executive and judicial departments. The enacting clause expressed the purpose of the Constitution and set forth its sanction in the will of the people. The existing State constitutions contain, in addition to the foregoing, a good deal of ordinary legislative matter, inserted from time to time by State constitutional conventions for

the purpose of putting it beyond the reach of ordinary legislatures. Some of this matter is important, such as measures for the regulation of the liquor traffic, but much of it is comparatively trivial.

The Suffrage.—The fundamental organ of government in the States is the electorate. The right to vote was originally conferred only on those who were deemed to have a sufficient interest in the welfare of the State and who were otherwise fit. Manhood suffrage did not exist. During the first half of the 19th century it was established in substantially all the States, so far as white men were concerned, and after the Civil War the ballot was extended to the freedmen. Meanwhile a reaction had set in against the principle of manhood suffrage. First, literacy qualifications were established in several northern States to exclude uneducated foreign-born voters and then qualifications of various kinds were established in the southern States to exclude Negro voters. At present qualifications designed to restrict the franchise to those who are deemed fit exist in just half the States. The extension of the ballot to women on the same terms as to men began in the territories of the west. Equal suffrage for men and women now exists in more than a third of the States, and in several others women may vote for presidential electors and most local officers, though not for governor and members of the State legislature. There is a larger number in which they may vote in certain local elections, particularly in public school elections. The 19th Amendment to the Federal Constitution will, however, put an end to disfranchisement on account of sex. In most States the voters must be registered, at least in the larger cities, in order to exercise their right. In most States also the ballots are printed and elections are conducted by public officials at public expense. The collection and expenditure of money by candidates for election and by political parties is generally regulated by law and corrupt practices are carefully defined and prohibited.

State Legislatures.—The State legislatures consist of two branches. The lower branch, generally called the house of representatives, contains as a rule from two to three times as many members as the upper, which is always called the Senate. The number of members of the lower branch ranges from 35 in Arizona and Delaware to 402 in New Hampshire. The number of senators ranges from 17 in Delaware to 63 in Minnesota. In most States the county is the basis of representation in both branches of the legislature. Various methods of apportionment have been adopted for the purpose of adjusting representation more or less accurately to population, but in many States there is deliberate discrimination against the larger cities in the apportionment of members. The term of members of the lower branch is two years in almost all States, and that of senators in the majority of States is four years. Members of the legislature are paid in all States. In most States the rates are low; in some they are no more than the wages of unskilled manual laborers. In most States the legislature meet regularly once in two years and the length of the session is gen-

erally limited to 60 or 90 days. Both the powers and the procedure of the legislatures are more or less strictly limited by the State constitutions. The legislative powers are conferred equally on both branches, with the exception that money bills must originate in the lower. The senates are also entrusted with certain executive and judicial powers, notably the power of confirming executive appointments and of trying impeachments when brought by the lower branch. In practice the latter power has proved of little importance, whilst the former has made the Senate an exceedingly important factor in executive affairs in all States where the executive has much patronage. In general the working of the legislatures has been the least satisfactory feature of State government.

The Governor.—Most of the State constitutions declare that the governor shall be the chief executive magistrate, but few constitutions actually confer on him the powers necessary and appropriate for a chief executive. His principal associates are generally elected, like himself, directly by the people, and for terms as long as his own. It is consequently impossible for him to direct them in the conduct of their offices. Though in all States the governor may appoint some of the department heads and members of administrative boards and commissions, his power of removal is often surrounded with restrictions which render him more or less of a figurehead in the actual conduct of administration. The importance of the office of governor results mainly from its political powers, notably the power to recommend measures to the consideration of the legislature and to veto bills which though passed by the legislature are objectionable. In most States the veto power extends to the veto of items in appropriation bills, thus giving the governor a specially strong position with respect to appropriations. The State constitutions further provide that an executive veto may be overridden by special majorities in the legislature, but in several States, where a two-thirds majority of all the elected members in each branch is required to pass a measure over a veto, it is exceedingly difficult in practice to do it. Moreover in States where the length of legislative sessions is strictly limited, most of the measures are passed in the last days of the session and the executive veto is not exercised upon them until after the session has closed. Thus the governor has come to be the chief legislator rather than the chief executive of the State.

Administrative Agencies.—The expansion of the administrative activities of the States in recent years has caused a great increase in the number of separate administrative agencies. In New York there were more than 150 separate administrative agencies in 1915 and in several States there were over 100. Some of these separate administrative agencies, such as tax commissions, railroad and public service commissions, industrial commissions and departments of health and various special boards and offices charged with the administration of laws for the regulation of industry and the protection of labor, exercise important powers. In practice they are much more subject to control by the courts than by the

nominal chief executive of the State. In a few States appointments to minor places in the administrative service are made from lists of applicants certified as competent by State civil service commissions, but in most States appointments are made by the governor or the department heads at their discretion, except so far as limited by the requirement of senatorial confirmation or by special conditions laid down by law. In general, political considerations outweigh considerations of fitness too often for the good of the public service. Economy and efficiency in State administration tend to suffer from neglect.

The Judiciary.—The State judiciary are elected directly by the people in three-fourths of the States. In the others they are appointed by the governor or elected by the legislature. In the central and western States popular election is universal. Terms of Supreme Court judges vary from two years in Vermont to 21 years in Pennsylvania, but in most States the term ranges from 6 to 12 years. In Massachusetts the judges hold office during good behavior, like Federal judges. Salaries, as in the case of other State elective officers, are in most States comparatively low. Terms of judges of lower courts are generally shorter and salaries lower. The organization of the courts is generally regulated in the State constitutions. In most States it is highly decentralized. Magistrates' courts of various kinds exercise a limited jurisdiction in the towns and cities, above them in most of the States are the County Courts, and between the latter and the highest court of the State there are as a rule one or more intermediate courts with varying original and appellate jurisdictions. The States are generally divided into fixed judicial districts in order to localize these intermediate courts, and a separate court with a prescribed number of judges is organized in each district. The resulting judicial system is highly inelastic and not infrequently uneconomical and inefficient. On the whole, however, the working of the judicial system is more satisfactory than that of either of the other principal departments of State government.

Amendment of State Constitutions.—Two different modes have been provided in almost all States for the revision and amendment of State constitutions. One is by the constitutional convention. The organization and procedure of constitutional conventions is far from uniform. In some States a convention may be called by the legislature at any time. In others the approval of a majority of the voters is required before a convention may be called. In some States the number and manner of election of delegates to a convention is regulated by the constitution. In others the legislature may determine the numbers and manner of election. Most conventions, however, are actually organized upon the model of the lower branch of the legislature. In some States a convention may put the revised constitution, when agreed upon, in force without further reference to the people. In most States reference to the people is required or is practised without any special requirement. The other mode of constitutional change is by the proposal of specific amendments by the legislature, subject to approval by a majority of the voters,

In some States a proposed amendment must be adopted by two successive legislatures before it can be submitted to the people. In others adoption by one legislature is enough. In all States the legislature must approve a proposed amendment by more than a bare majority vote. Recently beginning in Oregon in 1902, a fourth of the States have established another mode of constitutional amendment not requiring action by the legislature or by any other representative body. This is the so-called constitutional initiative. Upon petition of a prescribed number of voters a proposed amendment is placed directly on the ballot and may be adopted by a majority of the voters.

The Initiative.—A larger number of States, beginning with South Dakota in 1898, have established the statutory initiative. Upon petition of a prescribed number of voters an ordinary legislative measure may be proposed for adoption directly by the voters. This procedure for direct legislation by the people is generally associated with the direct popular referendum, a device by means of which the voters may veto a measure which, though enacted by the legislature, is objectionable to them. In 1919 the statutory initiative existed in 19 States and the popular referendum in 21 States. In some of these, notably Oregon, California, Arizona and Colorado, the initiative and referendum have been freely used in recent years.

Party System.—Actual government in the States is profoundly affected by the existence of the party system. In most of the States the political party is recognized by law as an instrument of government. In all of them the nomination of candidates for elective office is entirely in their control, and to a considerable extent the nomination of candidates for appointive office is practically vested in the leaders of the party organizations. A political party is commonly defined as an association of voters which at the last preceding election polled not less than a certain number of votes, or a certain percentage of the total vote for some representative office. This qualification is usually easy to meet. A political party, when recognized, becomes entitled to the exclusive use of a party name and, in most States where illiterates may vote, also a party emblem, which assists the illiterate in marking his ballot. The number of recognized parties varies, but in most States is at least three and in some as many as six. Only two parties, however, are anywhere of major importance, and in many States one of these is generally much more successful than the other. In most States the major parties are now required to make their nominations at primary elections, which are conducted by public election officers at public expense. In some of these States the voter may attend the official primaries and help nominate the candidates of any party he chooses without divulging his party affiliation. In the greater number of States, however, he must declare his party affiliation before he can participate in the nomination of candidates, the voters' declarations being checked by a system of party enrolment. The organization of the parties also is commonly regulated by law, and the members of the party committees, like the candidates for public office,

are selected at the primaries. The regulation by law of the methods of nomination has been accomplished for the most part within the last quarter of a century, and the establishment of the direct primary system has been the work of the last 15 years. Taken together with the introduction of the Australian, or secret official ballot, the legal recognition of parties and the regulation of their proceedings has brought a great improvement in the conduct of elections and in the general tone of politics in the States. See APPOINTMENTS, FEDERAL, STATE AND LOCAL; APPORTIONMENT; APPROPRIATIONS, AMERICAN SYSTEM OF; BUDGET; FEDERAL GOVERNMENT; LEGISLATION; LEGISLATURE.

STATE GOVERNMENTS, Characteristics of. As a federation, the government of the United States comprises the national government controlled by its legislative and administrative departments, and the separate governments of the 48 States of the Union. Under the national Constitution, each State may organize its government system as it pleases, but it must be republican in form, or organized so that the will of its citizens can be ascertained and enforced. When forming the Union under the Constitution of 1787, the 13 original States reserved to themselves certain characteristic rights, which the Federal government is bound by fundamental law to respect. These can be reduced only by amendments to the Constitution. Nearly all forms and powers of government were comprised in the sphere of State authority with the exception of those relating to foreign affairs, army and navy, interstate commerce, coinage and the tariff, the powers of the national government being specified in the fundamental law. The individuality, the dignity of the sovereign State, the only gov-

ernment officially known to foreign states, is represented by the national government possessing the powers involved in international relations, including war and diplomacy. In domestic matters, general economic interests are under its control. By contrast, the States control the mass of governmental power in respect to life, property and education and legislate freely on property rights, occupations, crimes, charities, sanitation and schools. Except import and export taxes, each State may levy what taxes it pleases; and it may legislate for the general welfare of its citizens subject only to the few restrictions of the national Constitution. The differences of taxation and legislation in each State form their distinctive characteristics. See *STATE; TAXATION; UNITED STATES—STATES CONSTITUTIONS*; and articles on the different States of the Union.

STATE MILITIA. See *MILITIA*.

STATE SYSTEMS OF EDUCATION.

The government of the United States has never exercised control or supervision over public education. The American people were not prepared for a national system of education when the foundation of the national government was established by the adoption of the Constitution of the United States. That document does not, therefore, contain a single provision in relation to the subject of education. There was not that common mutual interest in the social, industrial, commercial and political relations between the several States which later gradually developed among them. There was much prejudice and even fear against the power of a centralized national government. The idea of State control in all matters possible prevailed to a large extent among the people of all the States. While the subject of education was not regarded generally by the national leaders as one to receive their consideration, there were men in all parts of the country who recognized the vital need of establishing schools for the education of all children. Even in colonial days this idea had strong support in many of the colonies, notably in Massachusetts, New York, Connecticut, Rhode Island, New Jersey and Pennsylvania. The Dutch settlers brought with them the ideas of governmental institutions which prevailed in Holland. In the Dutch settlements schools had generally been established. The English Dissenters also brought with them their beliefs on social problems and they also organized schools in their settlements. When States were organized and institutions were being developed to meet the social needs of a progressive people, the influences which had been created by these forces were bound to be a potent factor. In these States, therefore, the establishment of schools received early consideration. The British evacuated the City of New York in November 1783, and within two months from that time Governor George Clinton was urging upon the legislature of New York the need of schools in the following language:

"Neglect of the education of youth is among the evils consequent on war—perhaps there is scarce anything more worthy your attention, than the revival and encouragement of seminaries of learning; and nothing by which we can more satisfactorily express our gratitude to the Supreme Being for his past favors; since piety and virtue are generally the offspring of an enlightened understanding."

Gradually each State by legislative enactment either continued the schools established by the colony or authorized the establishment of new schools. In many cases special acts conferred upon a particular community the authority to maintain a school. The general laws authorizing and requiring all communities in the State to provide schools were enacted. State aid was gradually extended. Thus through a process of legislation there was gradually established a system of education in every State in the Union. By this method the accepted policy of the nation in relation to public education was adopted and that policy is the voluntary action of each State in organizing and maintaining a State system of public education. When the practice of a State upon a subject has been continued for a long period of years so that such practice becomes the fixed policy of the State, the people of the State usually express that policy in their State constitution. When new States are admitted to the Union such States adopt a constitution, and it has been the settled practice of the newer States to incorporate in their constitutions a provision requiring the maintenance of a system of free schools. As the constitutions of older States have been revised a provision relating to education has been incorporated in such constitutions. The State of New York, which enacted a general law establishing a State-wide school system in 1812, did not include an article in her constitution in relation to education until 1894.

Nearly every State in the Union has written in its constitution a provision requiring the maintenance of a system of free common schools. These constitutional provisions are similar to the following:

MINNESOTA (sec. I, art. 8).—"The stability of a republican form of government depending mainly upon the intelligence of the people, it shall be the duty of the Legislature to establish a general and uniform system of public schools."

OKLAHOMA (sec. I, art. 13).—"The Legislature shall establish and maintain a system of free schools wherein all the children of the State may be educated."

NEW YORK (sec. I, art. 9).—"The Legislature shall provide for the maintenance and support of a system of free common schools, wherein all the children of this State may be educated."

It must not be inferred that, because the national government has not assumed direction and control of education throughout the country, it has not been interested in public education. On the contrary, the government has given aid in various forms to the support of education in the States for nearly a century.

In 1836 the national government distributed several million dollars of surplus funds among the States. In 1862 the National Land Grant Act was passed. This was followed by the Second Morrill Act, the Nelson Law, the Adams Law, the Smith-Lever Law and, in 1917, by the Smith-Hughes Act. The national government has given for public education nearly one hundred million acres of land. It has also established various agencies which exercise functions in relation to the educational affairs of the country. The Bureau of Education in the Department of the Interior and the Federal Board for Vocational Education are two important agencies dealing with education. It appears that more than 80 other agencies, which have official relations in one way or another with the school systems of the several States, have also been estab-

lished by the national government. There is now pending before Congress a bill creating a national department of education, whose head shall be a member of the President's Cabinet and known as Secretary of Education. Notwithstanding this aid to education on the part of the national government, and the activities of the nation in promoting the interests of education throughout the country, education in America remains subject to the control and direction of the several States. Even under the terms of the bill pending in Congress the control of education by the several States remains undisturbed.

Under this general plan which has been followed in administering educational affairs, there has grown up in America a fundamental principle of school administration which is becoming more pronounced and more controlling year by year. That principle is that education is a *State function* and that all the schools of a State constitute *one system—a State system*. In other words, the schools maintained in a city or a school district are not independent, detached systems, but they are a part of the State system and subject to general control and direction by the State. The fact that local officers are selected by popular vote or are appointed by a mayor does not make these officers local or city officers, or the schools local or city schools. These school officers are officers chosen by a method determined by the State and for the performance of State functions, and the schools are a part of a State system.

There is probably no question related to the administration of public schools which is of greater importance at the present time than the distinction between local control and State control. All powers exercised by local school officers in the administration of schools are powers delegated by the State through legislative enactment and may be modified or revoked by the agency which conferred them. Local control often means municipal control, and the greatest obstacle that has stood in the way of educational progress in the cities of this country has been the control or domination of school affairs by municipal officers. Where such domination has existed the schools have very generally been administered upon the same political and partisan bases which have governed the administration of municipal affairs. In several of the leading cities of the country the mayors and other municipal officers are attempting to override the statutes regulating the administration of the schools, to obtain control of the management of such schools and to establish the general policy under which they shall be governed. This interference of municipal officers has resulted in legislation in many States to make more secure the right and the authority of school officers to administer the schools.

The decisions of the courts have uniformly, in the several States, sustained the cardinal principle that education is a matter of general concern to the State and subject to the State's general control and direction.

An examination of the leading cases decided by the courts of the several States in relation to the control and supervision of public education will show that the following fundamental principles of school administration have been clearly established.

1. Public education is a State function or a subject under the control and supervision of the State. Systems of education which have been established in the several States but administered by local officers in the several localities of the State are State systems.

2. The officers chosen to administer laws enacted to operate and maintain a school system in various localities throughout the State are not local officers, neither are they town, village or city officers but public or State officers performing duties for the public at large.

3. When the officers of a city are authorized to perform some duty in connection with the operation or maintenance of public schools, as the appointment of members of a board of education by the mayor or the collection of taxes for school purposes by a city treasurer, such city officers do not act, in the discharge of such duties, as municipal officers but as special officers exercising a power devolved upon them to administer a function of government for the benefit of all the citizens of the State.

4. The laws relating to the schools of a city which are written in the charter of such city are a part of the school laws of the State and not a part of the charter or law of the city.

In support of these fundamental principles the following excerpts are taken from leading court decisions:

"The power of the States to establish and maintain systems of common schools, to raise money for that purpose by taxation, and to govern, control and regulate such schools when established is one of 'the powers not delegated to the United States by the constitution nor prohibited by it to the States; and consequently it is reserved to the States respectively or to their people.'" (Marshall v. Donovan, 10 Bush [Ky.] 690).

"It is apparent from the general drift of the argument that the learned counsel for the defendant is of the opinion that the employment of the teachers in the public schools and the general conduct and management of the schools is a city function in the same sense as it is in the case of the care of the streets or the employment of police and the payment of their salaries and compensation; but that view of the relations of the city to public education, if entertained, is an obvious mistake. The city can not rent, build or buy a schoolhouse; it can not employ or discharge a teacher, and has no power to contract with teachers with respect to their compensation. There is no contract or official relation, express or implied, between the teachers and the city. All this results from the settled policy of the State from an early date to divorce the business of public education from all other municipal interests or business, and to take charge of it as a peculiar and separate function through agents of its own selection, and immediately subject and responsive to its own control. To this end it is enacted in the general laws of the State that all school trustees and boards of education shall be corporations with corporate powers, which, of course, includes the power to sue and be sued in all matters relating to the control and management of the schools." (Gunnison v. Board of Education, 176 N. Y. 11).

"If only elected or appointed in accordance with the mandates of the law to perform a duty which is neither local or corporate, and if they are independent of the corporation in the tenure of their office, and the mode of discharging its duties, they are not servants or agents of the corporation, but public or State officers, with such powers and duties as the statute prescribes, and no action lies against the corporation for their acts or negligence." (Ham v. Mayor, 70 N. Y. 459).

"He is an employee of the board of education. It is not a part of the corporation of the city of Brooklyn, but is itself a local school corporation, like every board of school district trustees throughout the State (general corporation law, sec. 3), and is like every such board an integral part of the general school system of the State. It is a State and not a city agency, doing State and not city work and functions. Education is not city, village, county or town business. It is a matter belonging to the State government. From the comprehensive foundation by chapter 75 of the Laws of 1795, down to the recent codification of our school laws ('Consolidated School Law,' Laws of 1894, ch. 556), our State system of education has remained a consistent whole." (Ridenour v. Board of Education, 15 Misc. 418).

"Where the duties which are imposed upon municipalities are of the latter class, they are generally to be performed by officers who, though deriving their appointment from the corporation itself, through the nomination of some of its executive agents, by a power devolved thereon as a convenient mode of exercising a function of government, are yet the officers, and hence the servants, of the public at large. They have powers and perform duties for the benefit of all the citizens, and are not under the control of the municipality which has no benefit in its corporate capacity from the performance thereof. They are not then the agents or servants of the municipal corporation, but are public officers, agents or servants of the public at large, and the corporation is not responsible for their acts or omissions, nor for the acts or omissions of the subordinates by them appointed. And where a municipal corporation elects or appoints an officer, in obedience to an act of the Legislature, to perform a public service, in which the corporation has no private interest and from which it derives no special benefit or advantage in its corporate capacity, such officer can not be regarded as a servant or agent of the municipality, for whose negligence or want of skill it can be held liable. It has appointed or elected him, in pursuance of a duty laid upon it by law, for the general welfare of the inhabitants or of the community. He is the person selected by it as the authority empowered by law to make selections; but when selected and its power exhausted he is not its agent, he is the agent of the public for whom and for whose purposes he was selected." (Maxmillian v. Mayor, 62 N. Y. 164).

"Essentially and intrinsically the schools in which are educated and trained the children who are to become the rulers of this commonwealth are matters of State, and not of local jurisdiction. In such matters, the State is a unit, and the Legislature the source of power. The authority over schools and school affairs is not necessarily a distributive one to be exercised by local instrumentalities; but, on the contrary, it is a central power residing in the Legislature of the State." (Clark v. Haworth, 122 Ind. 465).

"The only function of these trustees is the management of the school and they are officers of the school rather than of the county." (State v. Freeman, 61 Kan. 90).

"The word *system* as used in the constitution means an organized plan, an institution, something established for the use and benefit of the people so long as the want of public education will continue." (Peay v. Talbot & Bros., 39 Tex. 346).

The following cases are also cited as having a very direct and vital bearing upon the proposition:

In 1876 James N. Gerard, inspector of schools in the city of New York, was elected to the State senate. His seat in that body was contested by his opponent, William Laimbeer, upon the ground that the constitution provided that a municipal officer shall not be eligible to election to the legislature. The committee on judiciary reported adversely to the claim of the petitioner and on its recommendation the senate adopted the following preamble and resolution:

"Whereas, In the judgment of the Senate, an inspector of common schools in the city of New York is not an officer under the city government within the meaning of the eighth section of the third article of the constitution of this State; therefore, *Resolved*, That the prayer of the petitioner be denied." (N. Y. Senate Journal, 1876, page 209).

In 1881 the late State commissioner of education, Dr. Andrew S. Draper, was a member of the board of education of the city of Albany. He was elected to the assembly. His seat was also contested upon the same ground that the seat of Senator Gerard was contested. The report of the committee on contested seats, which was an exhaustive treatment of the question and to the effect that a member of a board of education was not a municipal officer, was unanimously adopted. (Assembly Journal, 1881, Volume 1, pages 716-727).

It is not contended, not even suggested, that the State control and direction of education which is urged in this article means a State monopoly of educational affairs. Such a scheme of education would be repugnant to the whole American idea of education. State *direction* and *control* of public education means simply that the State shall clearly assert its duty and

obligation to the people and shall guarantee to them full protection in their rights and needs in a matter so vital to their happiness and prosperity. It has been a wise procedure on the part of the States to establish in their State school organizations a local school autonomy. Such action gives to a community the right to provide school facilities which shall not only satisfy the standard prescribed by the State, but to provide even higher standards if the wealth, the commercial needs and prosperity, the social and intellectual attainments, and the sentiment of their people will support them.

The administration of public education on the basis of the State instead of the nation has resulted in great inequality of educational facilities in the various States of the Union. Some States, because of their wealth and population, are able to provide for the children of such States school facilities which cannot be provided by the sparsely settled and less wealthy States. It is unnecessary to enumerate all of these inequalities, but some are indicated. The school term ranges in the several States from 108 days per year to 194 days per year. In 11 States the period of the school term is less than 140 days. The average number of days which each child attends school ranges from 55 in one State to 134 in another. In 20 of the States the average number of days in the school term is 90 or less, and in 30 of the States it does not exceed 100 days. The expense per capita of the average day's attendance in North Carolina is \$12.31, while it is \$86.36 in Montana. The minimum period of compulsory attendance ranges from four months in one State to the full school year in 30 States. It may be said, however, that in several States having a compulsory attendance law, such law is not enforced. It should be further noted that it has taken one-half a century of hard work to write into the statutes the compulsory attendance laws of the several States.

The difference in the qualifications of teachers provided for the schools of the several States also results in an inequality of educational opportunity for the children residing in such States. It is known that in some States young people 16 years of age, and even under such age, are employed as teachers. In 19 of the States there is no minimum age requirement for teachers employed in the public schools. In a majority of the States large numbers of teachers are employed whose education has been obtained solely in the elementary school. In many States the authority to teach is determined entirely by an examination based on preliminary subjects only.

In 26 States the salary paid the chief executive or supervisory school officer is not above \$3,000 and runs as low as \$1,800. In one of the States the State superintendent of public instruction is chosen at the general election, having been nominated at a direct primary, for a period of two years. He receives a salary of \$2,500. His duties are defined in the law as follows:

"To have general supervision of the public schools; keep official records, etc., at his office in the State capitol; furnish to county examiners questions for the examination of teachers; furnish blanks, registers, etc., to county examiners for use of school officers; prepare and furnish poll books for use at school elections; aid commissioners of the school fund in the administration of the same; make annual report to the governor as to the condition of the schools and the school fund, which report shall be transmitted to the legislature;

apportion annually to counties the State school funds on the basis of number of persons between 6 and 21 years old; have school laws published and distribute the same; give opinions as to construction of school laws."

This official is a fiscal school officer under the duties imposed upon him by law and not a leader directing and stimulating the educational affairs of his State.

A constitutional mandate requiring the maintenance of free schools throughout a State must be interpreted to mean that so far as possible the system of common schools established throughout the State shall provide *equal* educational opportunities for all the children of the State. It does not mean that a State school system may be established which must of necessity, by its very form of organization, give to the children of one section of the State or of any community in the State educational facilities which are denied the children of another section or of another community. It must also be held that, under this provision of the constitution, a State school system must be established which imposes equal burdens upon the taxpayers who support such system. Inequality of taxation for school purposes is inequality of educational opportunity. A school system, therefore, whose administration imposes an inequality of taxation and which does not provide equal educational opportunities does not conform to the letter or the spirit of the constitution and should be modified.

In many States funds have been established, the revenue of which is used for the support and maintenance of schools. In nearly all States provision is made by which funds are appropriated from the State treasury for the support and maintenance of schools, and apportioned by the chief school officer of the State to the various districts or cities in the State. In some States, as in California, New York, Pennsylvania, New Jersey, Minnesota and Washington, large appropriations are made by the State for the support of the schools. The balance which is needed in any district or city to meet the expense of the maintenance of schools, after applying State funds, is raised by local taxation. Nearly all the States maintain State normal schools for the training of teachers for the public school system, and not only construct the buildings at State expense but meet all the expenses of maintenance and operation.

There is a tendency in legislation on educational matters to follow the general policy of the whole country in legislation upon other important subjects, and to establish in a greater degree State uniformity, direction and supervision in educational matters. In several States provision has been made for minimum salaries of teachers, for the uniform certification of teachers, for the retirement of teachers, for the supervision of schools, for compulsory attendance, for medical inspection and health instruction of pupils, and for the construction of sanitary and safe school buildings.

In some States the administration of public education is highly centralized under the direction of the chief educational officer of the State. This is notably true in the State of New York. In such State the commissioner of education prescribes the conditions on which students may enter State normal schools; he prescribes the courses of study in the State

normal schools; he has the final approval of teachers appointed in such institutions and he appoints the members of the local boards in charge of the administration of such schools. The examination and certification of teachers is in accordance with rules and regulations which he prescribes; he is authorized by law to prescribe, by regulation, the functions of district superintendents who supervise rural schools; he may also, by regulation, impose upon city superintendents and boards of education throughout the State duties in the administration of the schools; he may condemn schoolhouses in any part of the State and require new buildings to be erected; he has judicial authority in determining all school controversies arising throughout the State, and his decisions in such matters are final and not subject to review by the courts. The tendency throughout the country is strongly toward greater centralization. This is due to the fact that education is more and more recognized as a matter to which the State must give more careful direction and supervision. A law which is State-wide can be made stronger and more effective than a local law. A general statute is respected more by the public, and is, therefore, more readily enforced, than a local statute.

There are three distinct systems of local administration of schools in operation in this country. These are known as the district system, the township system and the county system. The district system is the one which was first established. When it was first necessary to organize schools a few families living in the same neighborhood associated themselves together, employed a teacher and maintained a school. When school systems were organized in States which had adopted this system, the organization already established was utilized and in some of the States, as in New York, that system is still in operation. In each town throughout a State in which this system is in operation there are several separate school districts. Each of these districts maintains an independent organization with its own local officers, and each is a tax district; so that in each township there are all the way from 8 to 35 separate and independent authorities in charge of the schools of a single town, and possessing the power to assess taxes upon the property of such districts for the maintenance of schools. This kind of an organization for the administration of rural schools has been demonstrated to be cumbersome, obsolete and inefficient. This system has been discontinued in many States and must be in all States before rural schools can be improved and modernized and enabled to serve the people of the agricultural sections as the schools should and as present conditions demand.

In New England and many of the western States, the township is the unit of administration. Under such systems a town board of education is usually chosen at a town school meeting and is given general authority over the supervision and administration of all the schools of a town. In other words, it is the substitution, in rural communities, of an economical and professional system in the administration of schools for the inefficient and unbusinesslike plan which is followed in school districts generally where the school district sys-

tem is in operation. It gives all the schools of a town the same businesslike management which is generally afforded in cities where all the schools are under the control and supervision of one board of education. In most of the western States the general form of government followed in administering public affairs has been followed in the administration of school matters. In these States, the county is the unit of school administration. Where this system prevails, there is a county board of education and a county superintendent of schools. These officers perform the functions which are generally performed in towns and districts by the town and district boards.

The local school officers, whether under the district, town, or county system, have the direct charge of the administration and operation of the schools. These officers employ the teachers, determine the period of time school must be maintained beyond the period required by law, determine the salary to be paid in advance of that required by statute, make repairs to buildings, construct new buildings, purchase supplies and equipment, and perform such other functions as may be required to operate the schools or to make effective a State plan of education.

A sound, effective, equitable State system of education must rest upon a legal foundation similar to the following:

1. There should be a constitutional mandate which requires the legislature to provide for a free system of common schools. This constitutional provision should require school officers for every unit of school administration in the State, with powers not conditioned in any way whatever upon the action of municipal officers. It should also provide for raising such funds as are necessary for the operation of the schools. In other words the absolute management and control of the schools, independent of all local municipal authority, should be guaranteed the school authorities by the constitution. It should further require the establishment of a State department of education with sufficient authority to administer a sound, progressive educational policy.

2. The legislature should confer on the chief educational officer of the State sufficient power and provide him with sufficient funds to be a real leader of power and influence in directing and supervising the educational activities of the State.

3. A unit of school administration and taxation for the rural communities should be established, embracing not less than the territory of the town, so that rural school facilities may be provided which shall be equal, so far as may be possible, to the facilities provided in the cities and other populous centres.

4. State aid in much larger proportion than has yet been provided should be furnished and distributed upon a basis which shall enable the community having less property values to maintain schools which shall give the children in these less favored sections advantages as nearly equal as may be possible to those advantages afforded children whose homes are in more favored centres.

THOMAS E. FINEGAN,
Deputy Commissioner of Education and As-
sistant Commissioner for Elementary Educa-
tion of the State of New York.

STATE TAXATION. See TAXATION.

STATE UNIVERSITIES, The. General Statement.—The history of education hardly offers a parallel to the rise and growth of State-supported institutions for higher learning in the United States during the latter part of the 19th and the first decade of the 20th century. In 1875 20 such institutions had been founded but a very few had risen to any kind of educational prominence. They had at that time a total registration of 2,340 students. In 1885 26 institutions enrolled 4,599 students. In 1903 36 institutions enrolled 41,369 students. On 30 June 1917, according to the latest available figures issued by the United States Bureau of Education, there were 90 institutions in the States and Territories of the Republic supported in whole or in part by public funds and offering collegiate or professional courses beyond the range of the secondary school, with faculties numbering 12,368 persons, a total enrolment of 138,838 students and a total annual working income of upward of \$60,000,000.

This movement is not only unrivaled in the history of education; it is also perhaps the most significant and promising development in the history of our democracy. The sentiment which supports the movement is practically universal and it is the product of the spirit of the pioneers of the Central and Western States. Thirty-nine States now tax themselves without stint to provide a practically free education for their sons and for their daughters from the kindergarten through the college, and in many instances through the professional school as well. The nine States which do not have regularly designated State-supported universities, nevertheless contribute very generously to the support of higher education and maintain or help to maintain institutions which serve in part at least to perform the functions so admirably performed by such typical State universities as those in Michigan, Minnesota, Wisconsin and Illinois. The nine States which do not have State universities, as the term is now commonly understood, are Connecticut, Delaware, Maryland, Massachusetts, New Hampshire, New Jersey, New York, Pennsylvania and Rhode Island.

No people have ever before carried forward such a movement on any similar scale. In the early days Massachusetts and Connecticut and New York and New Jersey gave substantial aid to Harvard and Yale and Columbia and Princeton, but without any idea of becoming responsible for their permanent support and management. The common thought as to the functions of government touching education would not permit more than State aid and encouragement to a university in the colonial days or even in the earlier years of the Republic. The settlement of the great West opened the way for a new educational order of things. The pioneers built for the future, and they were especially anxious that ample provision should be made by the State for the education of their children.

Nearly all the State universities are open to women on an equal footing with men, and the tuition in collegiate courses is free or only a nominal sum. The tuition in the professional schools is ordinarily higher but is not based upon the theory of an adequate financial re-

turn for the expense involved. Indeed, the State universities more than any other agency have been responsible for removing professional schools in recent years from the realm of commercial enterprises. This is particularly and fortunately true of the profession of medicine. The State universities in common with a few highly endowed and thoroughly reputable private institutions have demonstrated that the teaching of medicine, as it ought to be taught, is not and cannot be a profit-making business.

All classes are represented in the great student bodies of the typical State universities, but the middle class predominates overwhelmingly. There are many students who find it necessary to "work their way," and if they do it and sustain themselves in their university work they uniformly gain the respect they deserve for it. Young men and young women work side by side in classrooms and laboratories; they attend social gatherings in company, with little in the way of regulation which is not self-imposed, and with the very best results. Life is free and genuine and natural and earnest, and the sentiment of the campus is wholesome. More than that the spirit of the typical State university is widely regarded as the most splendid promise of our democracy.

Historical Development.—As has been indicated, although all the colleges established in early or colonial days were private corporations they were in nearly every instance the willing recipients of public bequests. This investment of public funds naturally carried with it the thought of State control, but the early colleges were all, more or less, under denominational supervision and did not satisfy the demands of the people as a whole. The growing spirit of democracy is responsible for the birth of the State university. Strangely enough as it may now seem because of the marvelous progress of public education, elementary, secondary and higher, in the North and West in recent decades, the South took the lead in this early movement for publicly supported institutions for higher learning. The constitution of North Carolina framed in 1776 provided that "all useful learning shall be promoted and encouraged in one or more universities." An institution was founded upon the provision of this clause in 1789 and came into the full control of the State in 1821. But the fullest development of the State university was to be reached in the newer States in the Middle West. The constitution of Indiana, which is typical, provided in 1819 that "It shall be the duty of the General Assembly as soon as circumstances will permit to provide by law for a general system of education ascending in regular gradation from township schools to State university, wherein tuition shall be gratis and equally open to all."

Impetus was given to the establishment of State universities in 1862 by the passage of the Morrill Act by Congress. This act granted to each State 30,000 acres of public land for each senator and representative in Congress to which the State was entitled under the census of 1860. All money derived from the sale of these lands was to be invested by the State in securities bearing interest at not less than 5 per cent, except that the legislature of the State might authorize the use of not more than 10 per

cent of the capital for the purchase of sites for a college or experimental farms. The interest was to be used for the endowment, support and maintenance of at least one college where the leading object should be to teach such branches of learning as are related to agriculture and the mechanic arts in order to promote the liberal and practical education of the industrial classes in the several pursuits and professions of life. Of the colleges benefiting under the act Kentucky, Mississippi, South Carolina and Virginia divide the income between an institution for whites and one for colored students. With the exception of Massachusetts which divides the fund between two colleges, each of the other States maintains one college or university to receive the benefit of the fund. Nineteen States have created and maintain independent colleges of agriculture and the mechanic arts while also maintaining State universities. In each of 21 States the college of agriculture is a part of the State university. Twenty-eight States were allotted 8,160,000 acres of land in scrip; 20 States received 2,890,000 acres in place. The scrip and lands have been sold for \$12,643,309.43. Each State now applies all the income for the support of the agricultural and mechanical college. The total income for 1913-14 was \$856,318.95. Among the State universities owing their origin to the Morrill Act are those of California, Illinois, Maine, Minnesota, Nebraska, Nevada, Ohio, West Virginia and Wyoming.

The State universities now existing in 39 different States were founded as shown in following table:

Alabama.....	1831	Nebraska.....	1879
Arizona.....	1891	Nevada.....	1886
Arkansas.....	1872	New Mexico.....	1891
California.....	1868	North Carolina.....	1789
Colorado.....	1877	North Dakota.....	1883
Florida.....	1884	Ohio.....	1870
Georgia.....	1785	Oklahoma.....	1892
Idaho.....	1889	Oregon.....	1876
Illinois.....	1868	South Carolina.....	1801
Indiana.....	1820	South Dakota.....	1882
Iowa.....	1847	Tennessee.....	1794
Kansas.....	1864	Texas.....	1883
Kentucky.....	1878	Utah.....	1850
Louisiana.....	1860	Vermont.....	1791
Maine.....	1867	Virginia.....	1825
Michigan.....	1837	Washington.....	1861
Minnesota.....	1868	West Virginia.....	1867
Mississippi.....	1848	Wisconsin.....	1848
Missouri.....	1840	Wyoming.....	1886
Montana.....	1895		

Resources and Revenues.—While the Morrill Act had much to do with the inception of State universities, as has been indicated, the income from the fund and from supplementary acts is a very small part of the amount now expended annually by the several States for the furtherance of higher education. The principal sources of income in addition to Federal land grants are student fees, gifts and State appropriations. As has been noted, fees are merely nominal in all under-graduate courses and are not calculated upon a commercial basis in the professional schools. While the State universities have never strongly relied upon gifts many have profited by donations at various times. This is notably true of Georgia, Indiana, Kansas, Michigan, Minnesota and North Carolina. The University of Virginia received a gift of \$2,000,000 in 1909 from Andrew Carnegie and others. The University of Wisconsin and the University of California have each been greatly enriched by private gifts. The

chief source of income, however, is from direct appropriations by the legislature. Several States now have a mill-tax for the university which makes assured provision for maintenance. Colorado, Illinois, Indiana, Kentucky, Michigan, Minnesota, Nebraska, Nevada, Ohio, Oregon, Utah, Washington, Wisconsin and Wyoming have a mill-tax rate. For the year ending 30 June 1917 the University of Illinois received \$2,111,629 from her mill-tax, the University of Michigan \$1,175,385 and the University of Wisconsin \$1,285,048.

Organization and Administration.—The supervision and control of the typical State university is vested in a board of regents or trustees usually appointed by the governor with the consent of the senate. In a few instances the regents or trustees are chosen by the people at a general State election. This is true in Illinois and Nebraska. There have been a few conspicuous departures from the general rule, but in the main these boards have been singularly free from political interference and have as a natural consequence drawn to their membership representative citizens generally interested in the promotion of sound education and been able to act disinterestedly upon all important questions coming before them. In Indiana University the alumni have a voice in the selection of the trustees, and the influence of the alumni is coming to be felt indirectly in the selection of governing boards throughout the country. It is not unusual to find one or more graduates on the board of an institution and the tendency in that direction is growing.

In practice the theory that boards legislate and individuals act or execute is the guiding principle in determining the relations of the governing board and the president. This principle of procedure has not been established without a struggle and regents or trustees without conception of their duties and with an inordinate desire to "run" their institutions have more than once caused serious trouble. The typical management of a State university today is not unlike that of the average bank where the board of directors act in an advisory capacity only and leave the management of the daily business of the bank entirely in the hands of the executive officers. Accordingly the position of president of a great State university is a dignified one and calls for well-trained executive powers as well as for seasoned scholarship. Almost universally the president is in fact as well as in name the real executive head of his institution, turning to his board for advice or for endorsement of general plans. In the matter of appointments and resignations upon the faculty the president initiates action and goes to his legislative board only for the confirmation or veto of his recommendations. Men like Angell at Michigan, Northrop at Minnesota and Draper at Illinois, through the free exercise of their great executive powers and by the force of their characters had much to do in determining methods of university procedure which have now widely become unwritten laws and which have in many instances, indeed, been written into university statutes.

While the president is given large executive powers, the very widest latitude in the interior management of the State university is given to the deans and the faculties of the several colleges and the relations of administrative offi-

cers and instructors are notably harmonious. The organization of the typical State university may be understood by noting the actual conditions at the University of Illinois. The board of trustees consists of 12 members, three of whom, the governor, the president of the State board of agriculture and the State superintendent of public instruction, are ex-officio members. The nine other members are elected by the people and serve for terms of six years each, three being elected every second year. The board appoints the president who is the general executive officer. The chief administrative officers below the president are the vice-president, the deans of the colleges, the registrar, the comptroller, the dean of men, the dean of women, the adviser to foreign students, the high-school visitor, the executive secretary, the director of the information office, the supervising architect, the university health officer, the director of physical training for men, the director of physical training for women, the professor and commandant in charge of military training, the university librarian and the curators of museums. The university is divided into the following colleges and schools: the College of Liberal Arts and Sciences; the College of Commerce and Business Administration, the College of Engineering, the College of Agriculture, the College of Law, the Graduate School, the Library School, the School of Music, the School of Education, the School of Railway Engineering and Administration, the One-Year Medical College, the Summer Session, the College of Medicine, the College of Dentistry and the School of Pharmacy.

It will be noted that the typical State university practically undertakes with the exception of theology to carry out the maxim of the famous founder of Cornell University, "I would found an institution where any person can find instruction in any study." The ideals of the State universities as a group were clearly defined by the National Association of State Universities in a report of its committee on standards, adopted in 1908:

"We may define a standard American university to be an institution: (1) which requires for admission the completion of the curriculum of a standard American high school with a four years' course . . . ; (2) which offers in the college of literature and science two years of general or liberal work, completing or supplementing the work of the high school; (3) which offers a further course of two years, so arranged that the student may begin work of university character leading to the bachelor's degree at the end and reaching forward to the continuation of this work in the graduate school or the professional school; (4) which offers professional courses based upon the completion of two years of collegiate work, in law or medicine or engineering; (5) which offers in the graduate school an adequate course leading to the degree of doctor of philosophy.

To be a standard university an institution shall be equipped to give instruction leading to the degree of doctor of philosophy in at least five departments, according to the standards prescribed in this report and shall have at least one university professional or technical school (which shall require) . . . the two years' collegiate training for admission."

Range of Instruction.—The permanent contributions of State universities to the cause of higher education is abundantly assured because the common sentiment of the people who support them encourages the universities to enter practically every field of scientific research and intellectual activity. Ancient and modern languages and literatures, rhetoric and oratory, history and philosophy, economics and sociology

and ethics, education and psychology, music and painting, mathematics, the earth and air and water and sky and life sciences, medicine and pharmacy and dentistry and law, every phase of agriculture and horticulture, the raising of wheat and corn as well as of horses and sheep, dairying and homemaking, architecture, civil engineering, electrical engineering, mechanical engineering, municipal and sanitary engineering, railway engineering, mining engineering, library science, business administration, physical training, and every other interest which stirs the intellect and challenges thorough study are grouped in separate colleges, schools or departments, with the necessary libraries and laboratories and farms and shops for the most practical and effective work. Military training under the immediate charge of United States army officers has long been a feature of the practical and productive work of the State universities. The drill and the study of military tactics usually continue for the first two years of the course. The students, or cadets as they are sometimes designated, wear uniforms, drill with army rifles, engage in sham battles and other manoeuvres, and are ordinarily led in dress parade by their own military band. This military training has long been regarded of great value to the physical well-being of the men and has been proved to be immensely worth while to the nation. The officers and men who had their initial military training in university battalions gave a good account of themselves in the war with Spain and the gallant and intelligent service of the many thousands who joined the colors in the Great War with Germany testified to the wisdom of the practice and gives assurance that even larger attention will be given to such training in the future. On the whole it can be said that the students welcome the drills and the accompanying taste of military discipline and it is certain that they are universally glad of the experience as they look back upon it. The State universities have a unique opportunity to lead the nation in a permanent program for adequate preparedness in the future.

Place in the Educational System.—The State universities in many instances, and especially in the Middle West, are a deliberately planned and component part of the educational system of their States. The educational system in a State which emphasizes such a plan may be said to cover 16 years, eight in the elementary school, four in the high school and four in the college. The articulation of the different parts is complete. The grammar-school graduate passes into the high school without examination and the graduate of the approved high school enters his State university without examination. The State university in such an instance is the natural capstone of the State's educational system. The relation of the State universities very generally to the schools below, and especially to the high schools, is intimate and helpful. The relation has its personal and human side due to the intelligent and tactful activity of university high-school visitors whose business it is to visit and inspect high schools for the maintenance of an accredited entrance list. Cordial relations are also further cemented by frequent conferences at the universities of superintendents and principals and teachers

upon topics of mutual interest. The high schools are invigorated and inspired by contact with the universities and the universities are kept sane in their entrance requirements by intimate knowledge of the capacity of their prospective students.

Social Life.—The social life at the universities is ordinarily democratic and wholesome. Greek-letter fraternities for men and sororities for women, national in character, have after many vicissitudes proved their right to permanent place in university life. They are now rarely frowned upon and are often encouraged by university faculties. Many of them have permanent homes at the university seat and contribute largely to the comfort and social opportunity of their members. They also are coming to be a means of aiding rather than of hindering university discipline and are frequently employed by tactful college officers in forming and directing student sentiment and action. The relation of men and women students is on the whole helpful to both sexes. The social and college intermingling of men and women is natural, and the disadvantages of a co-educational system, if there are any, are hardly thought of in a great State university. Physical training for men and for women is everywhere emphasized and class and club and fraternity games are very common. Athletics—basketball, football, baseball and track and field sports—occupy the spare time of the students and are valued more by college authorities than the public ordinarily understands as means of creating healthy college spirit and of controlling the enthusiasm of youth. The military band, glee and mandolin clubs, literary and scientific societies also contribute to the enrichment of university life.

Progress and Future.—The older state universities may now be said to have passed the creative or building stage. Their growth and development has been unprecedented, but it has not been without heroic struggle. The people in every commonwealth almost, especially in the Middle West and the Far West, have been united in their desire for a State institution of higher learning, but they have rarely known how best to go about creating and building such an institution. It has remained for educational statesmen—and it has called for statesmanship of the highest order—to lay down the guiding policies and educate the public to a right appreciation of its university. Singularly enough—and yet in a certain sense naturally enough too—the very public which has sought to promote the university has steadfastly insisted that it should prove its worth step by step. Hardly a State university has not gone through the period of being an outcast in the eyes of its own constituents. This means that patience and tact and disinterested public service is woven into the fabric of every one of them. The elementary scope of their progress is now well nigh over. Legislatures need no longer be convinced of their legitimate place and function in the life of the commonwealth, they no longer have to be haled into the open court of public opinion to establish reputable character. They have *arrived* in the minds of the public.

For the last two or three decades much has been heard—sometimes directly from their own press bureaus—about the growth of their

appropriations, the size and number and cost of their buildings, the number of their students and in general the "bigness" of their work. This prevailing note has been natural because the material growth of the State universities has of itself changed the educational map of the United States. The enduring service and the progress that is in the long run to count the most is to come through the building of the invisible universities within and without the magnificent walls that have been set up. The bringing together of trained teachers and scholars, the creation of libraries and laboratories and museums that shall do *fine* as well as *large* things, the searching out of new truths, the widening of human knowledge, the leadership of the State in the promotion of health, creature comforts for the masses, sound administration of public affairs—these are the things that are beginning to characterize the State university of to-day and that will undoubtedly signalize its service in the future. There is no better endowment than the will of a great free people for better things and this is the continuing heritage of the State universities.

HARLAN H. HORNER,
Dean of the State College for Teachers, Albany,
N. Y.

STATE UNIVERSITY. See AMERICAN UNIVERSITY AND COLLEGE, THE.

STATEN (stāt'n) **ISLAND**, N. Y., in the southeastern part of the State, is separated from Long Island by The Narrows and New York Bay, from Manhattan Island by New York Bay, from New Jersey by Kill Von Kull, Newark Bay, Arthur Kill and Staten Island Sound. Staten Island was discovered by Henry Hudson in 1609, and its first settlers were Dutch. It is about 14 miles long and five miles wide. The surface is somewhat hilly along the coast; in some parts there are bluffs. The island constituted the county of Richmond and had a county government until 1898, when it became a part of New York City under the name of Borough of Richmond. It is chiefly a residential suburb of the Borough of Manhattan, but in the interior are farm lands, and there is considerable manufacturing. Fort Wadsworth, on the east coast, at the entrance to The Narrows, is one of the most important fortifications in the United States. The improved road system of the island embraces over 200 miles of highways. The police force of New York City has headquarters, detective bureau and four police precincts on Staten Island. The city fire department also affords fire protection to all the larger places on the island. Education is well looked after throughout Staten Island, which has many good private schools, two large high schools, one in Saint George and the other in Tottenville, and 34 public schools. It has, therefore, become one of the favorite residential sections of New York City. The borough is divided into five wards; but the villages which were incorporated before the island became part of New York retain their Federal post-office organizations independent of the New York post office. Some of the largest post offices are at Port Richmond, New Brighton, Stapleton, Tompkinsville, Saint George, Tottenville and Rosebank. During the Revolutionary War Staten Island was occu-

pied by a large body of British soldiers, and their old fortifications form historic landmarks to-day. Pop. about 200,000. Consult Mershon, S. L., 'The Major and the Queen' (New York 1915); 'Staten Island Illustrated' (New York 1911); 'Staten Island and Staten Islanders' (New York); 'Historical Guide of the City of New York' (New York).

STATEN (stāt'n or stā'tën) **ISLAND**, South America, belonging to the archipelago off the southeast coast of Tierra del Fuego, and virtually a continuation of the same, extends for 38 miles from northeast to southwest between Capes Saint John and Saint Bartholomew, and is separated from Argentina by the Strait of Le Maire. It rises in Mount Buckland to a height of 3,000 feet. The peak is covered with snow, the slopes verdant in evergreens, shrubs and plants. There is great humidity or rain at all times, and the temperature is even. The chief harbor, among several excellent ones, is Port Cook, on the northeastern coast. This island was formerly an important whaling station for the English.

STATES, Admission of. No specific form of procedure is provided in the National Constitution for the admission of new States to the Union. Different methods of admission have marked the addition of the 35 States to the original 13. For admission, however, certain conditions must exist. The community must be organized with a population in numbers and character capable of upholding self-government, and Congress is the final judge whether these requirements are in evidence. The decisions of Congress, however, have often been influenced by party reasons, and in 1872 it was enacted that no State should be admitted thereafter unless "having the necessary population to entitle it to at least one representative according to the ratio of representation fixed by this bill." The action of a Congress, however, does not appear to have a binding effect on subsequent Congresses, for in contravention of this act Nevada, Wyoming and Idaho among other States were admitted. To gain admission, a petition is presented to Congress, which grants an enabling act if the request is favorably received. While these acts vary in details, the general principles define the boundaries of the new State, authorize the people to frame a State constitution, fix the mode of its formation and adoption, prescribe rules of suffrage for election purposes, set forth such provisions as Congress requires to be inserted in the document and provide for its submission to Congress or the President for approval. When all the terms of the enabling act have been complied with, Congress by resolution, or the President by proclamation, declares the new State admitted to the Union. Consult Beard, C. A., 'American Government and Politics' (1910); Dunning, W. A., 'Essays on the Civil War and Reconstruction' (1898); Hart, A. B., 'Actual Government' (1908); Poore, B. P., 'Charters and Constitutions' (1877); Thorpe, F. N., 'Federal and State Constitutions' (1909); Willoughby, W. W., 'American Constitutional System' (1904).

STATES, Classification of. States or nations may be classified according to: (a) the extent of the political state; (b) the structure of the political state; (c) the structure of the

government. In political science a state is understood to be a body of people inhabiting a given territory, organized for common purposes, independent of external control and supreme in the enactment and enforcement of law within the state territory. For the enactment and for the execution of law, and for international interchange, it is essential that the state be organized for public purposes. Without a definite political organization, no body of people can be recognized as having international status. This organization must be adequate to ascertain and express the public will and must have supreme power to subordinate all other wills to that which is taken as the will of the state. The essential marks of sovereignty are independence without and supremacy within.

States may be democratic, oligarchic, or autocratic. A democratic state is one in which the social state dominates the political. In an oligarchic or aristocratic state the social state relatively is a small part of the political. In an autocratic state political power is supposed to be vested in a single person. As democracies, republics and monarchies, states may be classified as: (a) Pure democracies, in which nearly all functions of government and especially legislation are performed directly by the political state; (2) republics, in which representatives chosen directly or indirectly by the political state carry on nearly all the functions of government, including legislation and adjudication; (c) monarchies, in which the head of the administration owes his position to birth rather than to personal choice by the political state. A state is oligarchic or aristocratic, if the members of a branch of the government owe their position to birth or some other cause independent of the will of the political state, as in the British House of Lords, the upper house or senate of the imperial legislature, where the members hold their position by hereditary title, and some by virtue of holding some other office. But with a few aristocratic survivals, the British Empire constitutes a democratic monarchy, republican in fact, and so are most modern monarchical states, the monarch being really little else than the hereditary president of a more or less democratic republic.

The organization of the political state may also determine its classification. It may be either centralized or federal, if (a) the will is determined in mass, as in France; or (b) if the will of the state is determined by balancing the separate will of a series of fundamental groups, as in the United States, Switzerland and in Germany. The well-being of the social state as a whole is the purpose of all political organization, and a centralized government may be more efficient than a federal government, but where intelligence and education are generally diffused among a people self-reliant and mutually tolerant, a federal government is more responsive to the variety of ideas which may characterize a large state, and is more likely to be permanent. Autocracy may attain high efficiency but is usually attended by tyranny. While a democracy has a republican form of government, a republic is distinguished by an oligarchic tendency, and a monarchy may be democratic or oligarchic, as well as autocratic.

The most practical form of state appears to be a republic with powers delegated to the government. With the nominal exception of Canada, all North and South American states have adopted this form, also France, Switzerland, Portugal and China and in 1919 the newly formed European states. Consult Dealey, J. Q., 'Development of the State' (1909); Willoughby, W. W., 'Nature of the State' (1896); Wilson, W., 'The State' (rev. ed., 1909).

STATES OF THE CHURCH. See CHURCH STATES.

STATE'S EVIDENCE is a term applied to evidence in a criminal case, in the form of a confession of one who committed or participated in the commission of a crime, and to be admissible it must be freely and voluntarily made. The equivalent law term in England and throughout the English-speaking British possessions is king's evidence (or queen's evidence). There is no provision in the law to make a state's evidence agreement legal or binding, yet such an agreement is frequently made and adhered to on the part of the State and countenanced by the court, as a means of securing the conviction of other criminals. In case where confession has been obtained under promise of immunity from the law, and the witness thus making the confession is subsequently placed on trial, it is a general practice not to use his confession against him. There is a general tendency in the courts of many of the States of the Union not to convict a defendant upon the uncorroborated evidence of an accomplice. See ACCESSORY; ACCOMPLICE; PRINCIPAL.

STATES-GENERAL, the name given in France till 1789 to the general assemblies of the deputies of the three orders of the nation, the clergy, nobility and the third estate (*bourgeoisie*). When peers were present it was not as forming a separate body but as the representatives of their order. The right of convoking the states, belonged to the king, to the regent, or the lieutenant-general of the kingdom. There was nothing fixed as to the number of electors or deputies, nor as to the conditions entitling one to vote or to be elected. As far back as the time of Charlemagne, and probably earlier, clergy and nobles assembled twice a year to deliberate on matters of public interest and importance. After about 100 years of active life these assemblies seem to have died, or to have been suspended; and it was not until 1302 that the States-General were first convoked by Philip the Fair to support the quarrel of the king with Pope Boniface VIII. Six years later the States-General, at the instance of the king, condemned the Knights Templars. The States-General had no power of making laws, but they served as a check on the arbitrary power of the sovereigns through their ability to give expression to the will or displeasure of the people. But as the States-General became more exacting of the sovereign, and the latter, through his increasing military power, more and more independent of the popular will, the States-General were less and less frequently called together. In 200 years they assembled only twice at the call of the king, once in 1614, and again in 1789. On this latter date

they assumed to themselves the title of National Assembly, and that of States-General was never afterward revived in France. See FRANCE—HISTORY B.C. 58 TO A.D. 1796.

The name of States-General is also given to the legislative assembly of the kingdom of the Netherlands, in which there are also provincial states for local government.

STATES RELATIONS SERVICE. See AGRICULTURE, DEPARTMENT OF.

STATES or STATE RIGHTS, in a federal government, the rights of the several States in their constitutional relations to the central or national government. In United States history the term has played a prominent part since the early years of the 19th century, and especially during the period immediately preceding the Civil War, when it represented the prevailing view in the Southern States regarding the relation of those States to the Union. Out of this view developed the doctrine of nullification and the attempts to put it into practice; and the doctrine of secession as put to practical test in the Civil War, the final issue of which made an end of the State-rights view in its former constitutional aspects. See CONFEDERATE STATES OF AMERICA; GOVERNMENT; NULLIFICATION; UNITED STATES—STATE CONSTITUTIONS; DARTMOUTH COLLEGE CASE.

STATESBORO, Ga., city and county-seat of Bullock County, 42 miles northwest of Savannah, on the Savannah and Statesboro and the Central of Georgia railroads. The First Congressional District Agriculture College is located here. The district is devoted principally to the production of melons and cotton, and there is a cottonseed-oil mill. Pop. 2,529.

STATESVILLE, N. C., city, county-seat of Iredell County, on the Southern Railroad, about 43 miles north of Charlotte and 20 miles northwest of Salisbury. It is in an agricultural and stock-raising region in which there is also considerable corundum mining. Cotton, grain and tobacco are cultivated extensively. The chief manufacturing establishments are cotton and tobacco factories, flour and lumber mills, tanneries, foundries and ironworks. The trade is chiefly in grain and cotton and tobacco products. There are seven churches and public and private schools. Pop. 6,000.

STATHAM, stăt'əm, Henry Heathcote, English architect and musical critic; b. 11 Jan. 1839. He studied architecture in Liverpool and practised there for a time, but removed to London about 1870, and since 1883 has been editor of *The Builder*. He has written much on both architecture and music, and was for many years musical critic to the *Edinburgh Review*. For several years in succession he gave classical organ recitals on Sunday afternoons at Albert Hall, London. He has published 'Architecture for General Readers'; 'Modern Architecture'; 'Architecture Among the Poets'; 'My Thoughts on Music and Musicians'; 'Winged Words'; 'The Organ and its Place in Musical Art'; 'Critical History of Architecture'; 'What is Music' (1913); 'Form and Design in Music.' In addition he has written much on art, music and literature.

STATICE, stăt'i-sē, a genus of maritime or desert plants of the family *Plumbaginaceæ*, called sea-lavender, marsh rosemary, etc., and found chiefly in the northern hemisphere. They are usually perennials, with tufted, alternate leaves, sometimes becoming diminutive shrubs. The flowers are commonly borne in cymes or panicles, composed of one-sided spikes, and have scarious, membranous, funnel-shaped calyces, colored, but often of a different hue from that of the five long-clawed petals. The fruits are small astricles. Several species are cultivated, among them the Russian statice (*S. latifolia*), notable for its very thick, long, perennial root, which is used for tanning in its native country. It is a handsome border-plant, having a radical tuft of long leathery leaves, elliptical in shape, and very loose panicles of minute blue flowers sometimes measuring a yard across, and useful in bouquet-making on account of the delicate sprays. Certain species yield valuable remedies, and others are useful as fuel in the deserts of Afghanistan.

STATICS. See MECHANICS.

STATIONERS' HALL, the name of the hall of the "Master and Keepers or Wardens and Commonalty of the Mystery or Art of the Stationers of the City of London." The company was incorporated in 1557, and had, till the passing of the Copyright Act in 1842, an absolute monopoly, as all printers were obliged to serve an apprenticeship to a member of the company, and every publication was required to be "Entered at Stationers' Hall." This registration is no longer compulsory, but the practice of registering is still useful in making good claims of copyright. (See COPYRIGHT). Consult Arber, E. A., 'Transcript of Stationers' Registers, 1554-1640' (Vol. I, London 1875-94).

STATIONS (Latin *statio*, from *stare*, to stand) in the Roman Catholic Church, the name given to the Wednesday and Friday fasts. Tertullian says that the name is derived from military usage. On those days the Christian stood on guard and "watched in prayer." The word has another peculiar signification in the city of Rome. There certain of the churches are visited on stated days by clergy and people, and those churches are called Stations. But by the word stations are more usually understood the "Stations of the Cross," a very popular devotional exercise which is in use throughout the Catholic world. These stations are a series of 14 images or pictures ranged round the interior of a church or even along a public way, in which are represented 14 incidents in the life of Jesus on the day of his crucifixion, namely, Sentence of death pronounced by Pilate; Christ receiving the cross; his first fall; his meeting with his mother; the cross borne by Simon of Cyrene; Veronica wiping Christ's face with a handkerchief; his second fall; his words to the women of Jerusalem; his third fall; stripping him of his garments; his crucifixion; his death; taking the body down from the cross; the burial. The people move in procession from station to station, reciting prayers at each, and between stations chanting the Stabat Mater, one stanza at a time. (See VIA DOLOROSA). Consult

Thurston, H., 'The Stations of the Cross' (London 1906).

STATISTICAL METHOD. The. The word "statistics" was coined about the middle of the 18th century by Gottfried Achenwall, a professor at the University of Marburg. Achenwall derived the term from the Italian word "statista," meaning statesman, which, in its turn, came from the Latin "status," meaning state. E. A. W. Zimmerman, professor of Natural History at Brunswick, in 1787, in a work entitled 'A Political Survey of the Present State of Europe,' gave this history of the origin of the word and the science which it represents: "It is about 40 years ago that the branch of political knowledge which has for its object the actual and relative power of the several modern states, the power arising from their natural advantages, the industry and civilization of their inhabitants, and the wisdom of their governments has been formed, chiefly by the German writers into a separate science. . . . By the more convenient form it has now received . . . this science, distinguished by the new coined name of "Statistics," is become a favorite study in Germany."

At first the method of approach was descriptive, but it was inevitable that figures, because of their greater simplicity and compactness, should take a more and more prominent part in the development of the new science and finally replace the old verbal form of exposition. Next, as a man naturally pictures an object in terms of its most prominent characteristics, it was not long before the term "statistics" was transferred from the science to the compilation of the facts and figures involved and, finally, to the arrays of facts themselves. Thus we read in the first number of the Royal Statistical Society *Journal* issued in 1838-39, "'Statistics' may be said, in the words of the prospectus of this society, to be the ascertaining and bringing together of those facts which are calculated to illustrate the condition and prospects of society." The name, having once come to be applied to the data themselves, it was but a short step to the calling of any compilation of figures or facts, "statistics," which is the modern usage of the term, while the science itself has come to be called "The Statistical Method." The latter may be defined briefly as the science of analysis and exposition of quantitative or qualitative data secured through enumeration or experiment.

Application of Statistical Method. (a)

Scope.—From this definition it may be seen that the statistical method is found applied wherever compilation of facts are given and accurate conclusions therefrom are wanted. Perhaps the most common application is that of the governmental census. The most ancient of our literatures, including the Fourth Book of the Bible, the name of which denotes its reference to a statistical subject, abound in references to the taking of censuses in preparation for large undertakings, such as the building of pyramids, military campaigns, the distribution of lands, and the levying of taxes. In modern times the taking of the census has been made periodic—in the United States every 10 years—and has been developed along very extensive lines, not only gathering the data, but analyzing and illustrating them as well. The student

of statistics will find in these government reports a wonderful wealth of data on innumerable subjects.

But the Statistical Method is no longer confined to investigations such as the census, by governmental agencies for administrative or other purposes. To-day each large corporation has its statistician, and all policies of the concern are based on his findings. Very frequently a business concern has been changed from a losing venture to a great success by a new manager who installed scientific methods based on a statistical study of the conditions affecting the business. Rents of business locations in cities are determined by a study of the number of people who pass the place. In fact modern industrial development has come to depend more and more on statistical research. In the sciences, both physical and biological, the statistical method is of foremost importance. The chemists who were given the task of finding a suitable clay for spark plugs for the Liberty motor solved the problem by this method. New serums and medical treatments are now subjected to the severest statistical tests before they are accepted by the medical profession. Statistical analyses have enabled the chemist to predict the existence of unknown elements with given atomic weights; and the astronomer to predict eclipses and locate new planets. The whole doctrine of evolution and heredity rests on a statistical basis as shown by investigations of Mr. Francis Galton and Prof. Karl Pearson in the field of the mathematical theory of evolution, and by the work of Gregor Mendel and his followers along the lines of Mendel's Laws of Alternative Inheritance.

In the social sciences, especially in the field of economics, the statistical method is equally indispensable. No economist would attempt to arrive at a conclusion concerning the production or distribution of wealth without an exhaustive study of statistical data. Business men and economists alike are convinced that only when Congress bases its tariff legislation upon a scientific study of the natural resources and economic needs of the various parts of the country will an equitable tariff law be passed. Careful analysis of the effects of the English system of "out-relief," the granting of partial relief to paupers without sending them to the poorhouse, showed that the system was lowering wages and increasing instead of decreasing pauperism, thus producing a social evil which grew as it fed on itself. In economics and the other social sciences the old Roman proverb is pre-eminently true, "Sine numero nihil demonstrandum est."

In seeking to apply the statistical method to any line of investigation care must be taken to avoid certain errors likely to be encountered where statistical data are inaccurately compiled or carelessly applied. One of the most common causes of error in conclusions derived from statistical data is the lack of proper definition of the elements entering into the problem concerning which data are being gathered. Other errors arise from careless or premeditated abuse of data, correct in themselves, but leading to erroneous conclusions when improperly used. False statistical deductions may result from inaccuracy, from slovenliness in gathering or arranging data, from partial statement of truth,

from a comparison of heterogeneous qualities, or from lapses in logic. The man who thought he had discovered that eminent mathematicians were remarkable for their longevity was correct in his data, but careless in their application. He should have compared the average length of life of eminent mathematicians, not with the average length of life of all human beings including those who die in infancy, but with the average length of life of men who attain intellectual maturity. Again, it is manifestly unfair to judge the skill of the physician by the number of his patients who have died, without also considering the total number he treated. Such abuse of statistics as the use of the same set of figures to prove that prohibition does prohibit, and that it does not prohibit has, to some extent, destroyed the popular faith in statistics and is responsible for the often heard expression, "You can prove anything by figures." Statistics may be likened to a razor, a delicate and very effective tool when handled by an expert but very dangerous to an infant. While care must be taken that accuracy is preserved in the gathering of statistics too great minutiae in description defeats the object sought. If, for instance, we wish to study the distribution of wage-earners in industrial establishments we will find ourselves lost unless we effect a grouping into a few classes, as there is a rather small limit to the number of impressions which a mind can receive and hold at one time. Closely related to this error of excessive attention to minutiae of detail is the attempt at greater accuracy in statistical deductions than the facts themselves warrant. There is in statistics much swallowing of camels and straining at gnats. We are continually confronted with financial statistics carried out to the last cent when many of the individual items cannot be ascertained with any degree of certainty to within the nearest thousand, or even million. The young man who, wishing to know the circumference of a wagon wheel, multiplied the diameter, obtained with a 35-inch yard stick, with the value of π carried out to 18 decimals, is illustrative of our ingrained but untrained desire for accuracy. That no resultant can be more accurate than the least accurate of its constituents is an axiom that is altogether too often forgotten, and much time and labor have been spent in efforts to secure precision not warranted by the facts. On the other hand no statistical conclusions should be adopted without a statement indicating the degree of reliance which may be placed on them. It must be borne in mind that statistics is "the science of large numbers," that results obtained from a few cases cannot be considered representative and should, therefore, be received with due caution. It can readily be proved that the precision of a determination is proportional to the square root of the number of observations, but also that there is a limit beyond which it does not pay to carry the refinement.

b. Statistical Tables.—In employing the statistical method statistical tables, both simple and complex are constantly brought into use. To illustrate the construction of these we will use the problem, referred to in a previous paragraph, of the distribution of wage-earners in the United States. The 1910 census (Vol. VIII) divides the industrial establishments of this

country into the following seven classes: those employing 1 to 5 wage-earners; 6 to 20; 21 to 50; 51 to 100; 101 to 250; 251 to 1,000; and over 1,000. We construct a table with these seven classes in one column and in a second column enter the number of establishments in each class. For comparative study we now enter in a third column the number of establishments in each of these classes as given in the census of 1900. This suggests a fourth column giving the increase or decrease for each class, and still another column giving the proportions, expressed as percentages, which such increase or decrease bears to the figures given for the earlier of the two years. Such a table is called a simple statistical table. Similarly we may construct another table, but giving here the number of wage-earners in each class. A combination of the two into a double-column table, such as is given in the census of 1910, is called a complex statistical table. Applying to this the proper arithmetical operations gives numerous interesting and important facts.

c. The Use of the Relative.—While statistics are absolute facts, a study of them is really a study of relatives. In the above problem this was shown by the introduction of proportions. In that problem the number of establishments employing 1 to 5 wage-earners, or the number of employees, means little unless we also know the proportion which these numbers bear to the total. This proportion is, in general, best expressed as a percentage. In vital statistics, however, it has become customary to use a radix number; so many deaths per thousand, for instance. Except in actuarial mathematics, where the formulæ have been developed on this basis, the latter is not a good method, as it does not readily yield itself to mathematical treatment.

d. Graphic Methods.—To show vividly the facts compiled in statistical tables and the conclusions to be deduced therefrom the statistician uses various graphic illustrations. What the microscope is to the biologist and the telescope to the astronomer, of like importance is this mechanical interpretation or illustration of statistics to the statistician. The common housefly is to the casual observer an uninteresting and repulsive creature, but the microscope reveals it as an object of wondrous structure and beauty. Similarly a table giving the temperature, taken each half hour during a certain day, means very little to us, but the curve automatically drawn by a thermograph records the changes in temperature momentarily and still tells us its whole story at a glance.

To construct such a frequency curve, as it is called, where variation is reasonably continuous, as in the above problem, erect at equal intervals along a horizontal line a series of vertical lines called ordinates, proportional in length to the number of objects in the classes which they represent. Then join the tops of these ordinates in such a way as to make a smooth curve. Such a curve not only makes clear to us the fluctuations in the frequency of its variates, which in the table are effectively hidden, but it also enables us to make important comparisons. We may, for instance, draw, on the same diagram but in different colors or with different types of lines five curves representing the total gold and silver in the national treasury, and the amount of silver,

silver certificates and treasury notes in circulation at the end of each quarter for a number of years. We have thereby before us the whole financial history of the country during this period and are, furthermore, able to make both interesting and valuable deductions by comparisons of these curves. These curves play an especially important part in the physical and biological sciences as they enable the scientist to replace the rough approximations obtained from a few observations with the law governing the frequency distribution. As aids in interpolation and extrapolation these curves are indispensable. This branch of statistical inquiry has been developed to its present high stage of perfection by Prof. Karl Pearson, who, through his work on the 'Mathematical Theory of Evolution,' has breathed into the clay of dry statistical data a living soul.

Where variation is not continuous or where discrete objects are under consideration the histogram or pictogram are preferable. The histogram is merely a succession of rectangles obtained by drawing through the tops of the frequency ordinates lines parallel to the base. A common and effective pictogram is a circle

divided into sectors, the areas of the sectors being proportional to the magnitude of the respective objects under comparison. For instance, we can illustrate the relative values of the principal crops of Nebraska by dividing a circle into five sectors of the proper relative sizes and label them "corn," "wheat," "oats," "hay," and "all other crops." Or we can place, side by side, on equal bases, five rectangles whose altitudes are proportional to the values of these crops. A complex table can be illustrated by superimposing two such diagrams on each other, as shown in the preceding figure. The number of ways in which such illustrations can be made is limited only by the limits of human ingenuity.

e. The Use of the Average.—Because of the important part which they play in statistics, the statistical method has been defined by some writers as "the Science of Averages." Averages may be considered as types through which we get an adequate conception of groups of variates and by means of which comparisons with other groups may be effected. Thus, though men of any race may differ greatly in height, we still get a very fair conception of the relative stature of a Patagonian Indian,* an Englishman, and a Lapp when we learn that their average heights are six feet one inch, five feet seven inches, and five feet, respectively. The first real development of scientific methods in statistical study came about through the needs of astronomers for some means of securing accurate determinations from their ever growing stock of observational data. It was found errors of observation were symmetrically grouped about their arithmetic mean, where they were clustered most closely, and decreasing continuously and equally in number in accordance with a certain law, called the normal law of errors, as the observation receded in either direction from the mean.† This law, also known as the Law of Probability or the Law of Chance, was found by the great Belgian astronomer and mathematician, Jaques Quetelet, to govern not merely the distribution of errors of measurement of inanimate things, or direct the action of "blind chance," such as the manner in which coins, when tossed, turn up "heads" or "tails," but also the chance distributions in the animate world. Whether dealing with barometric pressure, human height or the size of plants the law was found to hold. Later it was found that where a bias exists, as, for instance, the inclination of the loaded coin to turn up one face more frequently than the other, or wages to taper off more rapidly to the lower limit, the law still held, but in a generalized form. The place of concentration which is no longer the mean has been called by Professor Pearson the "mode."

There are three forms of averages in common use, two of which have already been referred to. The three are the arithmetic mean, the median and the mode, the first being by far the most widely used. To these may be added

* Consult Pearson, 'Reconstruction of the Stature of Prehistoric Races' in Transaction Royal Phil. Soc. (1898).

† Given by the equation $y = \frac{1}{\sqrt{2\pi}c} e^{-\frac{(X-a)^2}{2c^2}}$ where y is the frequency of the deviation x from the mean a , c is a mathematical constant called the standard deviation, and e is the base of the natural system of logarithms.

FLOUR MILLS AND GRIST MILLS.—VALUE OF PRODUCTS FOR LEADING STATES, 1909 AND 1899.
(Millions of dollars.)

This pictogram shows us at a glance, and in a clear and striking manner, a number of important facts, as for instance: the actual values of the milling products of the more important milling states in 1899 and again in 1909, the growth of the industry in each state during this period, the relative importance of these states in 1899, and again, ten years later, which states have made the greatest progress, and which have been practically stationary.

the geometric and harmonic means, which, though seldom used, are indispensable in certain lines of investigation. The nature of the mode has already been described in the preceding paragraph. The median, meaning the

Normal probability curves illustrating the different degrees of skill of two marksmen, as indicated by the concentration of the hits about their centre of gravity in the one case and by their scattering in the other.

halfway point, is especially useful in dealing with non-measurable quantities, such as economic unrest, eye color or mental characteristics. We cannot for instance, state in figures the mental alertness of a class of boys, but we can readily arrange them in the order of their intelligence and thus determine the average boy. In a normal distribution the mean, the median and the mode naturally coincide. The arithmetic mean may be subdivided into the simple and the weighted. The simple arithmetic mean of two or more quantities is the sum of those divided by their number, without regard to their respective weights or relative importance. The weighted mean is the sum of the quantities, each multiplied by its weight, divided by the sum of the weights. The difference can best be pointed out by some examples. If we wish to find the average wage in an industry we cannot do this by simply

Moderately asymmetrical skew curve; ages of wives for given age of husband at marriage. *aa* mode; *bb* median; *cc* mean. The age of the bridegroom in this case is between 24 and 25 years, and the total number of marriages is 28,454. The mean age of the bride is 22.19 years while the modal age is 20.42 years. The age of the bride rises very rapidly from 15—16 years up to about 20 years, after which it tapers off rather slowly, the maximum age being 45 years.

averaging the scales of wages paid in the various occupations. If that were done the few, highly-paid experts and superintendents would count as much as the many common laborers and so give a very misleading conception as

to the wages really paid. The true average is obtained by weighting each wage by the number of men receiving that wage, adding the products and dividing by the number of men. In this case the weights are definitely determinable numbers, which is not always the case. An astronomer taking a series of observations on a certain evening will average these as equally good. When, however, he wishes to combine observations taken on different evenings he may consider these sets as of unequal value because of the unequal atmospheric conditions under which the observations were made. He will then use as weights numbers which, in his estimation, give the relative values of the observations.

An excellent example of the use of weights is afforded by the index numbers for the changes in wages or prices of commodities. In comparing prices of different years we find that, though some have increased and others have decreased, there has been a general tendency in one direction. To measure this tendency, that is, to determine the increase or decrease in the purchasing power of money, is one of the most important tasks of the economist. It is at once obvious that we cannot solve the problem by taking the simple arithmetic mean of the prices of all commodities, for that would unduly accentuate the lesser things; would, for instance, give matches as great weight as coal. Instead, we take the most important ones whose prices we can estimate rather accurately and tabulate for a number of years. Taking any year as a base year we can then express the prices of each other year as percentages of those of the base year. The properly weighted mean of these percentages will then measure the movement of prices during this interval.

In the use of the mean as a type it must be remembered that it will not fairly represent the group if there is too great a divergence from it within the group. For instance, statistics may show the same per capita wealth, say \$1,000, in two cities without giving us any idea as to the real prosperity of the inhabitants. The one city may have the wealth well distributed with all of its inhabitants prosperous and happy, while the other has its slums and its palaces with only a small middle class. If, however, to this per capita average is appended another figure showing limits within which half the people come, we can form a better estimate of the economic condition of the city. Suppose in the one case we find that this limit is \$100 in excess or defect of the mean while in the other it is \$400. We would then give the per capita wealth of the two cities as $\$1,000 \pm \100 and $\$1,000 \pm \400 , respectively. In the one case one-half the people fall within the narrow class of more than \$900 and less than \$1,100; in the other the limits would be \$600 and \$1,400. This additive quantity is called the probable error or probable deviation. We are, accordingly, in the development of the statistical method, interested not merely in the average as a type, but also in the divergence of the group from the type. The best measure of an average deviation from the mean is the so-called standard deviation, the square root of the mean of the squares of the deviations. Before we can compare the variabilities of two groups

we must first reduce their measures of dispersion to relatives by expressing them as percentages of the means. For instance, a difference of 1,000 pounds between the weights of two elephants is less, proportionately, than a difference of one ounce between the weights of two mice. Failure to recognize this principle has led some very eminent biologists into espousing theories absolutely at variance with the facts. But the statistician does not limit his study to the consideration of a single variable. One of his most important tasks is to analyze the relationship between one variable or phenomenon and another. He seeks, for instance, to find the correlation between poverty and crime, between the heights of fathers and of their sons, between the ages of husbands and of their wives, between the price of wheat and the marriage rate, between the size of the wheat kernel and its protein content, between vaccination and immunity from disease. We cannot, however, directly and definitely measure the effect of one variable on another because of the many other variables which enter into the problem. But by dealing with a large number of observations we can, to a large extent, neutralize these disturbing causes, and so make it possible to secure a very fair determination of the correlation between the two variables under consideration. We may, for instance, seek to determine the correlation between rainfall and the potato crop though recognizing that the size of the crop is a function, not merely of the amount of rainfall, but also of the temperature, culture, seed and a multitude of other causes. By dealing with a sufficiently large number of years, however, we can eliminate these disturbing elements and so secure an average value of the correlation sought. For the methods and formulæ used in this computation the reader is directed to Yule's work on the 'Theory of Statistics.'

CARL C. ENGBERG,
Executive Dean, the University of Nebraska.

STATISTICS is the science that deals with the collection, tabulation, analysis and presentation of numerical data. Any phenomena that may be classified and counted may be studied by the statistical method, in fact, no other method will yield a comprehensive, quantitative view of many kinds of phenomena. Statistics thus becomes the adjunct of all the sciences and the indispensable agency of governments in acquiring information concerning production, trade, distribution of wealth, unemployment, population, births, marriages, deaths, divorces, diseases, accidents and the many other matters on which the welfare of the state depends.

The principal functions of statistics are:
1. To furnish definite bases for comparison of related facts dealing with phenomena of the same or of different periods.

This function is well illustrated by the decennial census taken by the Federal government. Such census gives a comprehensive view of the population in all the various civil divisions of the country and enables comparisons to be made of the composition of the population in the several divisions with respect to age, sex, marital condition, nativity, citizenship, etc. The comparison of the data of the latest census with that of preceding censuses adds greatly to its significance. The facts relative to the increase or decrease of population and the changes in composition that have taken place during the 10-year period are fully as interesting and valuable as the data contained in the census itself.

2. To reveal laws underlying phenomena that could not be determined by individual observers.

In dealing with large numbers, by the statistical method, the constancy and uniformity of natural and social phenomena become apparent. In other words the laws underlying the phenomena are revealed. The mortality tables used by insurance companies constitute a practical illustration.

3. To show trends in phenomena that otherwise would be imperfectly known.

Changes in the trend of rates of birth, death, marriage, divorce, etc., are shown adequately only by statistics.

4. To reveal relations of cause and effect that otherwise would remain hidden.

The discovery by statistics of the relative longevity of total abstainers and moderate drinkers is a noteworthy example.

5. To serve as a guide for legislative, social and commercial action.

Statistics of dependents, delinquents and defectives are a prerequisite to the formulation of adequate statutes relating to these classes. The financial statistics compiled by the government and by commercial agencies are indispensable guides to investors, banking and other business houses and to the government itself.

Methods.—In the compilation of statistics three distinct processes are necessary, namely: 1. Collection of data; 2. Tabulation and charting of data; 3. Analysis and summarization of data. The collection of data comprises two separate steps: the preparation of blank schedules and the filling out of the blanks. The making of the schedule is a very important piece of work as on it depends the success or failure of the statistical undertaking. The principal points to be observed in preparing inquiry

blanks are: (a) The schedule must be made to fit in with the general tabulation scheme. The whole study must be very carefully thought out and a plan of tabulation made that will clearly show the answers to the general questions it is desired to ask. The schedule should contain the items needed for tabulation and nothing more. It is a serious mistake to load up an inquiry blank with superfluous or useless questions. (b) The schedule must give due regard to precedents. It is of the highest importance that the data obtained by the particular study should be comparable with those obtained in similar previous studies. If the study is one of a series taken at regular intervals, changes in standardized schedule items should not be made unless results had shown the necessity therefor. The study may be enlarged by adding new items but the continuity of the series should be preserved. (c) The schedules should be as clear and simple as possible. The captions or questions should be short and leave no doubt as to their meaning. Where necessary, brief explanations should accompany the items. (d) Except in institutions, questions should not relate to the habits, ability or private life of those expected to answer. It is obvious that the one replying will not place himself in an unfavorable light. (e) Schedules should be printed on sheets or cards of standard size so that no difficulty will be found in obtaining filing cabinets in which they will fit. (f) If the schedules are elaborate and are to be filled out by many different persons, they should be accompanied by a booklet of detailed instructions covering all the questionable points that might arise. If enumerators are sent out from a central office they should be given full instructions before beginning the work.

Statistical schedules are filled out in various ways. Census blanks are taken from house to house by paid enumerators who write in the information obtained by direct questioning. They are instructed to make all necessary explanations and to require answers to the questions asked, as refusal to answer is made a misdemeanor. Thus little difficulty is experienced in securing complete data. Statistics of births and deaths are usually obtained from schedules filled out by attending physicians. Statistics of inmates of institutions are best prepared by having uniform schedules filled out and sent to a central statistical office. Elaborate statistical reports on prepared schedules are obtained by the Interstate Commerce Commission and by public service commissions from companies operating public utilities. In order to make the reports comparable, uniform systems of accounting have been devised for companies of the various classes. The data now being collected from such companies are noteworthy examples of the efficient use of statistical methods. Labor bureaus secure data relative to wages and employment by sending questionnaires to employers and to labor unions and by means of special agents. Social and philanthropic organizations make special statistical studies or surveys by the use of questionnaires sent out by mail or by means of investigations made by field workers; the latter although of limited scope is usually more successful. When the schedules have been filled out and returned to the statistical office they must be examined for errors and incon-

sistencies and corrected before tabulation is undertaken. In spite of every precaution some mistakes will occur on the schedules and some desired data will be unascertained.

Two methods are used in presenting statistical data to the general reader, namely, tabulation and charting; the former is the primary method and is almost universal; the latter is supplemental and of limited use. The preparation of effective statistical tables requires good judgment and a thorough understanding of the significance of the data and of the questions that are to be answered by the tables. Although the numerical table is an end in statistical work the plan of tabulation must be decided upon before the schedule is prepared. The latter must be so formulated that it will furnish the information needed for the table. Tabulations should be as simple as the data will permit and should show only significant aggregates. The necessity of making the data comparable with corresponding data in previous studies must be borne in mind. Tabulations may be made either by sorting by hand and counting or by machines specially devised for such purpose. The number of cards and the kinds of tabulations to be made determine the method to be used. In census work, where elaborate studies of millions of individuals are made, machines are indispensable. Machine tabulation necessitates the use of codes whereby the data on the schedule card may be transferred to the card to be used in the machine by punching holes at prescribed places. The punching machines and cards are made to meet the requirements of the sorting and tabulating machines. The electric tabulating machines will make cross tabulations at the rate of 250 to 400 cards per minute.

Statistical charts or graphs are used to illustrate statistical tables. They make clear and emphasize the principal numerical results shown in the tables. To be effective, statistical charts must meet certain definite requirements: (a) They must be self-explanatory. Charts are useless if they can be understood only after reading lengthy explanations in the text or footnotes. (b) They must be simple. Complicated charts are more difficult to understand than statistical tables, and therefore fail in their purpose. (c) They must have unity, i.e., not more than one principal theme should be portrayed on a single chart. A large variety of graphic forms are used in making charts, the most common of which are points, bars, curves, areas and maps. The kind of statistical results to be shown determines the form to be used in any case. To standardize the use of diagrams, a joint committee on standards for graphic presentation representing 17 national societies was appointed in 1915. A preliminary report of this committee sets forth the following principles as applicable to elementary graphic presentation:

The general arrangement of a diagram should proceed from left to right.

Where possible, represent quantities by linear magnitudes, as areas or volumes are more likely to be misinterpreted.

For a curve the vertical scale, whenever practicable, should be so selected that the zero line will appear on the diagram.

If the zero line of the vertical scale will not normally appear on the curve diagram, the zero line should be shown by the use of a horizontal break in the diagram.

The zero lines of the scales for a curve should be sharply distinguished from the other co-ordinate lines.

For curves having a scale representing percentages, it is usually desirable to emphasize in some distinctive way the 100 per cent line or other line used as a basis of comparison.

When the scale of a diagram refers to dates, and the period represented is not a complete unit, it is better not to emphasize the first and last ordinates, since such a diagram does not represent the beginning or end of time.

When curves are drawn on logarithmic co-ordinates, the limiting lines of the diagram should each be at some power of 10 on the logarithmic scales.

It is advisable not to show any more co-ordinate lines than necessary to guide the eye in reading the diagram.

The curve lines of a diagram should be sharply distinguished from the ruling.

In curves representing a series of observations, it is advisable, whenever possible, to indicate clearly on the diagram all the points representing the separate observations.

The horizontal scale for curves should usually read from left to right and the vertical scale from bottom to top.

Figures for the scales of a diagram should be placed at the left and at the bottom or along the respective axes.

It is often desirable to include in the diagram the numerical data or formulae represented.

If numerical data are not included in the diagram it is desirable to give the data in tabular form accompanying the diagram.

All lettering and all figures on a diagram should be placed so as to be easily read from the base as the bottom, or from the right-hand edge of the diagram as the bottom.

The title of a diagram should be made as clear and complete as possible. Subtitles or descriptions should be added if necessary to insure clearness.

Ratios and Averages.—In presenting statistical information to the public it is generally necessary to publish the detailed tables showing the results of the original compilation. Such tables show the numerical relation of totals to totals in one category of data, or of a part or parts to a total, or a part to a part, or of a number of one category to a number of another category. Ratios may be expressed by common fractions, decimals, percentages, or rates per 1,000 or per 100,000, etc. Percentages are most commonly used but death and birth rates are usually expressed by the number per 1,000 of general population; and death rates from single diseases, by the number per 100,000. A common form of ratio in business and economic statistics is the number per capita, as money in circulation per capita, as wealth per capita, etc. Crop yield may be expressed as bushels per acre or tons per acre. Density of population is indicated by number of persons per square mile. The ratio to be used in any case is determined partly by custom and partly by the demands of clarity and conciseness of expression.

Averages form another indispensable aid to the statistician in the summarization of data. An average is a quantity which serves to characterize a number of divergent quantities. The purpose of averages is to express by a single item the net result of a series of items. The principal forms of averages used in statistics are the simple arithmetic mean, the weighted arithmetic mean, the geometric mean, the median and the mode. The simple arithmetic mean is most widely used. It is computed by dividing the sum of a series of numbers by their number. The weighted arithmetic mean is found by multiplying the numbers of a series by coefficients or weights of different sizes and dividing the sum of the products resulting by the sum of all the coefficients. The weighted average is used in cases where it is desirable to give greater emphasis to some items than to others. The geometric mean of a series of n items is the n th root of the product of the items. The use of the geometric mean in statistics is limited. Its principal value has been

found in the computation of index numbers. The median is that value which "has the central position in a series of items arranged according to size." (Czuber). If an odd number of items is arranged according to size, the median is the middle number of the series. If the number of items constituting the series is even, the median lies between the two central items. The median is less dependent upon extreme values than the arithmetic mean and may often be taken as typical of the series. The mode in a series of items is the value occurring most frequently and around which the other items are distributed most densely. As an average it is more typical than either the arithmetic mean or the median. The mode and median, however, can be computed only for a series of quantitative individual observations such as series of wages, incomes, etc.

Index Numbers.—Index numbers are used principally to indicate changes in prices or wages from one period to another. The prices of a certain period are arbitrarily taken as a standard and the index number of such period is fixed at 100. The prices in succeeding periods are computed as a percentage of those of the standard period, a general rise being indicated by an index number above 100 and a general decline by a number below 100. It is obvious that index numbers are valuable only for comparative purposes and that of themselves they give no indication of the values from which they are derived. The wide range of possibilities in the selection of commodities, prices and weights and in methods of computation has necessitated standardization of procedure which has been improved from time to time in recent years.

Dispersion.—Dispersion is a statistical term used to denote the variation in magnitude of the items constituting a series. It is measured by the difference in size of the extremes or by the general deviation of the items from the type. Such measurement may be absolute or relative. For purposes of comparison coefficients of dispersion are found by dividing the absolute measure of dispersion by the quantity representing the typical item. The most common measures of dispersion are known as the average deviation and the standard deviation; the former is found by dividing the sum of the deviations of the several items from the arithmetical mean, without regard to signs, by the number of items; the standard deviation is computed by dividing the sum of the squares of the several deviations from the arithmetical mean by the number of items and extracting the square root of the quotient. In series where the items represent different frequencies the standard deviation is found by multiplying the squares of the several deviations by the corresponding frequencies and dividing the sum of the products by the total frequencies and extracting the square root of the quotient.

Skewness.—Skewness in statistics denotes asymmetrical dispersion or that at points of like deviation above and below the mode the frequencies are unequal. Skewness is measured in various ways, the simplest measure being indicated by the difference between the arithmetical mean and the mode. The simplest coefficient of skewness is found by dividing the difference thus found by the average deviation

from the mode. Other coefficients are found by more complicated mathematical processes.

Correlation.—The determination of the causal relationship between two or more groups of phenomena known as correlation, constitutes one of the principal developments of statistics in recent years. While statistics alone are not able to prove causal relationships absolutely, they are able with other factors to furnish satisfactory demonstrations of the fact and extent of correlation in many realms of phenomena. Correlation between two statistical series may be shown by diagrams or by computation of the coefficient of correlation. The former method is used in statistical work designed for the general reader, as the correspondence of the two frequency curves on the diagram is recognized at a glance. The second method is used in cases where a definite measure of correlation is desired. The formula most commonly used in computing coefficients of correlation is that devised by the biologist Karl Pearson. Without attempting a full mathematical demonstration the method of computation may be briefly described as follows: Two series of items of equal length representing two groups of phenomena are taken. The one group may be designated as group *A* and the other as group *B*. The deviations from the arithmetical mean of the several items of each group are determined. The deviations in group *A* may be designated by x_1, x_2, x_3 , etc., and those of group *B* by y_1, y_2, y_3 , etc. The several deviations of the items of group *A* are multiplied by the deviations of the corresponding items of group *B* and the products are added. This summation of products is designated as $\Sigma(xy)$. The standard deviation of group *A* is designated as σ_1 and that of group *B* as σ_2 . The number of items is denoted by n . Then r , the coefficient of correlation of groups *A* and *B*, is determined by the following formula, $\frac{\Sigma(xy)}{n\sigma_1\sigma_2} = r$, stated in words, the sum of the products of the deviations as above obtained is divided by the product of the number of items and the standard deviations of the two groups. Modifications of the method are used in dealing with various kinds of phenomena, and elaborate formulæ have been devised to determine the coefficient of correlation of three or more groups of phenomena. Through the work of Pearson, Bowley, Yule, Persons and others, rapid development has taken place in mathematical statistics during recent years. Much of the work in this field, however, is of a theoretical nature and has limited application in general statistics.

History.—The beginnings of statistics are found in very early times. The ancient Egyptians compiled data concerning population and wealth preparatory to the building of the Pyramids, about 3050 B.C. There are accounts of statistical works in China as early as 2300 B.C. Two censuses of the Israelites are recorded in the book of Numbers. A census was taken in Greece for the purpose of levying taxes in 594 B.C. Athens took a census of population in 309 B.C. The Romans excelled every other nation of antiquity in making definite measurements. Besides making quinquennial enumerations of the population, they prepared surveys of the entire country including parts of the

provinces. They also kept records of births and deaths. It was many centuries after the fall of the Roman Empire before another comprehensive system of governmental statistics was established. Very few statistical records of value were made during the Middle Ages but occasional investigations were ordered by sovereigns. Pepin the Short in 758 and Charlemagne in 762 ordered the detailed description of church lands. The registries of lands in France taken at these and succeeding periods known as "Polyptiques" included an enumeration of the rural population. The best known census of this period is the "Domesday Book" prepared by order of William the Conqueror in 1088 A.D. The purpose of this was to acquaint the sovereign with the extent of his new dominion and the tenure of the various parcels of land. Sebastian Muenster, a Heidelberg professor, anticipated the field of comparative statistics by preparing a systematic treatise on the organization, wealth, armies, commerce, laws, etc., of ancient countries. Francesco Sansovino published a similar work in 1562, and Giovanni Botero, another in 1589. Pierre d'Avity, Seigneur de Montmarin, compiled a much more comprehensive and accurate treatise in the same field in 1614. The registration of deaths was begun in London in 1532 and was followed by that of baptisms by parish clergymen. In 1629 the distinction of sex was made in the record. In 1661 a noteworthy statistical advance was made by the publication by Capt. John Graunt of his 'Observations' on the London Bills of Mortality. He was the first to point out the regularity of social phenomena and the excess of male births over female. Caspar Neumann of Breslau in 1691 compiled data relative to 5,869 deaths from the parish records of that city and pointed out that the supposed fateful significance of the years seven and nine was unfounded. His work attracted the attention of Edmund Halley, the astronomer, who laid the foundations of scientific life insurance by calculating a mortality table from the data collected. Another noteworthy contribution of this period was the mathematical demonstration of the theory of probabilities by Jacques Bernouilli, a professor of Basel. The first to use the word *statistik* was Gottfried Achenwall, (1719–72) a professor of philosophy at the University of Göttingen. The word comes from the Italian *statista*, which denoted statesman. Achenwall in his book discussed matters that he believed of interest to the state, such as population, resources, constitutions, etc. The name statistics was introduced into England by Dr. Zimmerman about 1787 and was popularized by Sir John Sinclair in his 'Statistical Account of Scotland' (1791–99). Writings more of the nature of modern statistics are found in Sir William Petty's 'Political Arithmetick' (1691) and Süssmilch's 'Betrachtungen über die göttliche Ordnung in den Veränderungen des menschlichen Geschlechts aus der Geburt, dem Tode und der Fortpflanzung desselben erwiesen' (1741). The close of the 18th century and the beginning of the 19th marked the revival of census taking. The United States took its first decennial census of population in 1790. England and France began periodic census taking in 1801. The former country has continued the practice at 10-year intervals, but the latter after taking a

second census in 1806 took no further enumerations of population until 1836. From that year to 1901 four general censuses were taken; since 1901 a census of population has been taken in France every five years. Belgium took its first census in 1829. The analysis of this census by Quetelet contains noteworthy observations on the influence of age, sex, occupation, economic condition and season upon mortality. Upon the organization of the Belgium Statistical Central Commission in 1841, Quetelet became its president and continued to hold the office until his death in 1874. His work not only placed the statistics of his native country on a high plane but did much to raise the standards of statistical work throughout the world. The progress of statistics was accelerated by the founding of the Société de Statistique de Paris in 1803, the Royal Statistical Society of London in 1834, and the American Statistical Association in 1839. Each of these societies holds meetings periodically and publishes the papers presented by its members. The first meeting of the International Statistical Congress was held in Brussels in 1853. After holding eight additional meetings it was succeeded by the International Statistical Institute in 1885. These societies have done much to promote uniformity in statistical classifications, schedules and tables, and otherwise to advance the science. Since 1890 there has been wonderful expansion in the field of statistics. Practically every civilized country now takes periodic enumerations of its population, keeps continuous records of births, deaths, marriages and divorces, and prepares elaborate statistics relative to production, foreign and domestic commerce, finance, public utilities, labor, agriculture, education, immigration, etc. The United States made a great advance in 1902 by making the Census Bureau a permanent office. Previous to that time the bureau was organized anew every 10 years for the purpose of taking the general census and was discontinued when the work was completed. While national statistics has been expanding there has been an equally great extension of statistical work in States and cities. Massachusetts took the lead in State statistics by establishing a permanent bureau of statistics and labor in 1869. A similar bureau was established by Pennsylvania in 1872, by Connecticut in 1873, and by Ohio in 1877. Subsequently several other States took like action. With the enlargement of State activities during the past 30 years the need of adequate statistics has been met, in part at least, by creating bureaux of statistics within State departments. These bureaux publish annual statistics relating to finances, taxation, banking, insurance, intra-State commerce, labor conditions, public utilities, education, dependents, delinquents, defectives, deaths, births, disease, accidents, etc. Scarcely less important are the valuable statistics prepared by the principal cities of the country. These statistics deal with the functions of the city and the problems that the city is required to solve, such as education, housing, transportation, docks, pavements, water supply, electricity, gas, crime, fires, accidents and diseases. Noteworthy contributions to statistics are being made by various organizations such as insurance companies, banking houses, national sociological and philanthropic societies, etc. The insurance companies especially have

done remarkable work in studying health conditions in various parts of the world.

HORATIO M. POLLOCK,
Statistician and Editor, New York State Hospital Commission.

STATIUS, stā'shī-ūs, Publius Papinius, Roman poet: b. Naples, 61 A.D.; d. 101 A.D. His principal productions are two epic poems—the 'Thebais,' in 12 books, treating of the war of the seven princes against Thebes; and the 'Achilleis,' in two books, relating the achievements of Achilles, and incidents in his life previous to the Trojan war. The latter is unfinished. The style of Statius is bombastic and affected, often exhibiting the art of the declaimer rather than that of the poet; but he attracted general admiration in his own time, and even some modern critics have considered him inferior only to Virgil. He wrote some shorter poems, called 'Silvæ,' which have been distributed into five books, and some of these compositions are beautiful. A modern edition of the complete works of Statius is that of Queck (Leipzig 1854); and of the 'Silvæ,' the best are those of Markland (London 1728); Sillig (Dresden 1827); Bachrens (Leipzig 1876); Vollmer (Leipzig 1898); Klotz (Leipzig 1900); and Phillimore (1904); Pope, Howard, Lewis, Stater and Stephens have made translations from Statius. Consult Butler, E. H., 'Post-Augustan Poetry' (Oxford 1909); Schanz, M., 'Geschichte der römischen Litteratur' (Munich 1913); Teuffel, W. S., 'Geschichte der römischen Litteratur' (Leipzig 1910).

STATUARY HALL, National, the popular name of the historic chamber formerly used by the House of Representatives at Washington, and now utilized for the preservation of the statues of historic Americans. In this chamber Madison was inaugurated President in 1809 and again in 1813; and there Monroe was inaugurated for his second term in 1821, and there Millard Fillmore took the oath of office as President on 10 July 1850, following the death of President Taylor. This is the hall in which Henry Clay presided as speaker of the House in the old days. There occurred the stormy debates incident to the War of 1812 and the war with Mexico and the preliminary struggles over the vexed question of

slavery. There Daniel Webster and later Abraham Lincoln sat as obscure congressmen, each before the day of his meridian fame. There John Quincy Adams was chosen President in 1825 over Andrew Jackson and William H. Crawford, when the election was thrown into the House of Representatives. By the terms of an Act of Congress approved by President Lincoln on 2 July 1864, the chamber was officially designated as a national statuary hall, and an invitation was extended to all the States to contribute statues to be set up therein. Some 47 statues have been contributed by the different States of the Union; but the result of these contributions has not been altogether happy historically or artistically.

STATUTE, a law proceeding from the government of a state; a written law. Some ancient statutes in Europe are in the form of charters or ordinances, proceeding from the Crown. Statutes are either public or private (in the latter case affecting an individual or a company); but the term is usually restricted to public acts of a general and permanent character. Statutes are said to be declaratory of the law as it stood before their passing; remedial, to correct defects in the common law; and penal, imposing prohibitions and penalties. The term statute is commonly applied to the acts of a legislative body consisting of representatives. In monarchies not having representative bodies, the laws of the sovereign are called edicts, decrees, ordinances, rescripts, etc. See **LAW**.

STAUNTON, stā'n'ton, **SIR GEORGE THOMAS**, English traveler and Orientalist: b. near Salisbury, 26 May 1781; d. London, 10 Aug. 1859. He was the son of Sir George Leonard Staunton, 1st baronet, diplomat and Orientalist, and in 1792 accompanied his father to China and the Far East. He learned Chinese, returned to England for study at Trinity College, Cambridge, in 1797, and in 1798 entered the service of the East India Company, Canton, China. He succeeded his father as baronet in 1801, and in 1805, through his translation of Dr. George Pearson's treatise on the subject, was the means of introducing vaccination for smallpox into China. He returned permanently to England in 1817; served in Parliament in 1818-26, 1830-31, 1832-35 and 1838-52. He served on the East India Committee, and was one of the founders of the Royal Asiatic Society in 1823. He made the first translation of a Chinese work into English 'Ta Tsing leu lee, Being the Fundamental Laws of China' (1810); and was author of 'Miscellaneous Notices Relating to China' (1822); 'Notes of the British Embassy to Peking' (1824); 'Observations on Chinese Commerce' (1850), etc.

STAUNTON, Howard, English Shakespearean editor and pre-eminent as a chess-player: b. England, 1810; d. London, 22 June 1874. He was educated at Oxford, after leaving which he settled in London, and devoted himself to literary pursuits, and to chess, becoming the champion chess-player of his day. His first important publications were 'The Chess-player's Hand-book' (1847); 'Chess-player's Companion and Chess-player's Text-book' (1849); 'Chess Tournament' (1852); 'Chess Praxis' (1860). Before the appearance of

the last work he had begun the publication of an edition of Shakespeare, 1857-60, which was generally considered by the Shakespearean scholars of the day to furnish the best text that had till then been published. Later studies were given to the world in a series of papers on 'Unsuspected Corruptions of Shakespeare's Text,' begun in the 'Athenæum' in October 1872, and continued to the time of his death. He published 'Great Schools of England' (1865), and from 1844 till his death edited the chess column in the *Illustrated London News*. 'The Theory and Practice of Chess,' by Staunton and Wormald, appeared in 1876.

STAUNTON, Ill., city in Macoupin County, 37 miles northeast of Saint Louis, Mo., on the Litchfield and Madison and the Wabash railroads. Its industries are derived from the neighboring coal mines, gas and oil wells. It was settled in 1830. Pop. 6,495.

STAUNTON, Va., city, county-seat of Augusta County, on the Chesapeake and Ohio and on the Valley Branch of the Baltimore and Ohio railroads, about 40 miles northwest of Charlottesville and 55 miles north of Lynchburg. It was settled in 1745 by people from the northern part of Ireland. In 1802 it was incorporated and in 1871 it was chartered as a city. From its importance as a strategic point Staunton became the objective point of many campaigns of the Civil War, but was not occupied by the Union troops until 6 June 1864, when General Hunter entered the place without opposition and, after destroying the railroad several miles east and west of the place, and burning much public property and many warehouses, marched toward Lynchburg. (See **PIEDMONT, BATTLE OF**). It was again occupied by General Sheridan's cavalry 2 March 1865, and the railroad and public property were again destroyed. (See **WAYNESBOROUGH, BATTLE OF**; **SHENANDOAH VALLEY, MILITARY OPERATIONS IN**). Woodrow Wilson was born in Staunton. It is in an agriculture region and has considerable manufacturing interests. Its chief manufactures include chemicals, bricks, pen-nants, flour, organs, machine shop, foundry products, canned goods, agricultural machinery. The principal public buildings are the Western State Hospital for Lunatics, the Virginia School for the Deaf and Blind, 16 churches, and the schools. The educational institutions are the State school mentioned, the Mary Baldwin Seminary, Virginia Female Institute, Staunton Military Academy, two business colleges, two other private schools, and public and parish schools. The four banks have a combined capital of \$600,000; the annual amount of business is about \$30,000,000. The government is vested in a mayor and a council of 12 members, each of whom holds office two years. Pop. about 12,000.

STAUROLITE, STAUROTIDE, CROSS-STONE, or FAIRY-STONE, a mineral very frequently found in cross-shaped, penetration twins, whence its name (from Greek, *stauros*, a cross; *lithos*, a stone). It crystallizes in the orthorhombic system, the simple crystals being short prisms. Besides the twins above mentioned other forms abound. The crystals are usually rough and of a dark reddish-brown to brownish-black color. Hardness 7 to 7.5; specific gravity,

3.65 to 3.75; lustre somewhat resinous. It is a silicate of aluminum, iron and magnesium. It abounds in many of the crystalline schists, such as mica schist, argillaceous schist, and gneiss. Important occurrences are Monte Campione, Switzerland, and Fannin County, Ga., and in scores of localities in New England and North Carolina. It occurs sparingly in Brazil and North Carolina in transparent fragments which yield gems remarkable for their green to reddish-brown pleochroism.

STAVANGER, stā-vāng'gēr, Norway, capital of Stavanger County, a seaport on Bokn Fjord, 105 miles northwest of Christiansand. It has two excellent harbors with quays and docks, and is protected by islands. The Bay of Dusevik is a rendezvous for warships, and is visited more than any other port of Norway by merchant vessels. The principal buildings are the ancient Gothic cathedral, Saint Peter's Church, several schools, museum, hospital and mechanics' institute. The chief articles of export are herrings, anchovies, lobsters, sheep, butter, fertilizers and preserved foods, marble, oil and hides. There are some manufactures of woolen, linen and cotton goods, soaps, preserves, butter, oleomargarine, bricks, hardware, iron foundries and pottery, and distilleries, ship-building yards, a repairing slip and foundries. Kjelland, the novelist, was born at Stavanger. Pop. about 40,000.

STAVESACRE, a larkspur (*Delphinium staphisagria*), native to the Mediterranean region, whose seeds have been used medicinally since ancient times. It is a pubescent plant, about two feet high, with purplish flowers in terminal racemes. The seeds are grayish brown, reticulated with ridges, oily, and have an acrid and biting taste. They contain the poisonous principle delphinine, but were used as a purgative and emetic; being too powerful, their use at present is confined to an external remedy, in tincture, for rheumatism, and, in powder or ointment for killing parasitic vermin.

STAVROPOL, stāv'rō-poly, Russia, in the Caucasus, (1) capital of the government of Stavropol, on the Atchla, 307 miles southwest of Astrakhan. It is the seat of a Greek-Catholic bishop and is a well-built town. The schools include gymnasias for both sexes, and several town and industrial schools; there are also several libraries, and a people's palace. The manufactures comprise soap, leather and flour-mills, and there is considerable trade in hides, tallow and corn. The town was founded in 1776, and, on the commercial route between Russia and Persia, has flourished. Pop. over 60,000, (2) The government of Stavropol covers 23,398 square miles. The rainfall is scant, forests rare, the fauna and flora differ from other sections of the Caucasus, somewhat resembling central Asia. The inhabitants include Armenians, Greeks, Poles and Russians, about one-third being nomadic. On the wide prairies agriculture is carried on, and for this purpose various machines and implements are manufactured, and the products form the exports. Interesting is the communal tillage of lands, for the reserve fund of grain. The main streams are the Kuma and tributaries,

and in this section are the best lands. The Mantych is a lake-formed river, once a connecting link between the Black and Caspian seas. Near the Caspian are some unimportant salt lakes. Other small streams water the country at the west. The climate is characterized by sudden changes. Stavropol was early colonized but unsuccessfully, until the military colonies of Cossacks (1711) were established. After the emancipation of the serfs, immigration increased rapidly, and still grows. Population 1,300,000, principally Russians.

STAWELL, stā'ēl, a town of Victoria, Australia, 176 miles by rail northwest of Melbourne. The chief buildings are the municipal offices, some churches, mechanics' institute and theatre. The great quartz reefs of the Pleasant Creek gold-fields are extensively exploited, and large cyanide works are operated. Agriculture is an important industry; wheat, and vine-culture is especially carried on.

STEAD, stēd, **Albert**, English journalist and author, son of W. T. Stead (q.v.): b. 1877. He was educated at University College, London, and afterward served on the *Review of Reviews* under his father. He was sent as a correspondent to the different British possessions, and to the near and the far East. He became well versed in international politics, and lent his aid as a journalist to the Anglo-Japanese Alliance, and to the restoration of diplomatic relations between England and Serbia, which were broken upon the accession of King Peter after the murder of King Alexander and his consort. He was consul-general for Rumania in London in 1907-11; and in 1912-13 he was editor of the *Review of Reviews*. He was joint author of 'South Africa' (1899); and author of 'China and Her Mysteries' (1901); 'Japan, Our New Ally' (1902); 'Great Japan' (1905); 'Modern Roumania' (1908); 'Servia by the Servians' (1909); 'My Father' (1913), etc.

STEAD, Francis Herbert, English Congregational clergyman and social reformer: b. Howdon-on-Tyne, Northumberland, 20 Oct. 1857. He was educated at Owens Airedale colleges, Glasgow University and at the leading universities of Germany. He entered the Congregationalist ministry in 1884; was pastor at Leicester in 1884-90; and in 1890-92 edited the *Nonconformist and Independent*. He was appointed warden of the Robert Browning Settlement in 1894. He was instrumental in securing the appointment of the National Committee on Old Age Pensions in 1898; commenced an agitation for national old age homes in 1913; and in 1916 was convener of the League to Abolish War at a Third Hague Conference. He has written 'Hand Book on Young People's Guilds' (1889); 'How Old Age Pensions Began to Be' (1909); 'No More War, a Novel' (1917).

STEAD, William Thomas, English journalist: b. Embleton, 5 July 1849; d. at sea 15 April, 1912, one of the victims of the *Titanic* disaster. His father was a Congregational clergyman. He became editor of the *Northern Echo*, 1871; assistant editor *Pall Mall Gazette*, 1880, and in January 1890 founded the *Review*

of *Reviews* and similar publications in the United States and Australia. In July 1885 he published 'The Maiden Tribute to Modern Babylon.' For some of his acts in procuring evidence for this book he was arrested and imprisoned for three months. In 1893 he founded *Borderland*, a magazine devoted to occult subjects. He introduced American newspaper methods and ideas into England and he exercised a powerful influence on the government, which he was accused of, at times, forcing to do his will. He was noted as an advocate of permanent international peace and an undaunted champion of reform of social evils and civic administration. He wrote 'If Christ Came to Chicago'; 'The Pope and the New Era'; 'No Rent'; 'No Reduction'; 'Truth About Russia'; 'The Story that Transformed the World'; 'The Labor War in the United States'; 'Satan's Invisible World'; 'The United States of Europe'; 'Mr. Carnegie's Conundrum'; 'The Americanization of the World'; 'Peers or People'; 'Mrs. Booth'; 'The Despised Sex'; 'The Last Will and Testament of Cecil John Rhodes.' In 1898 his *War against War*, a weekly magazine, was founded to oppose the Anglo-Boer War. Consult Stead, Estelle W., 'My Father' (London 1913).

STEAM. Steam is water in a gaseous state. It liquefies at a temperature of 100° C., or 212° F., under a pressure of one atmosphere at the sea-level, namely, 14.7 pounds per square inch. High pressure and low pressure steam once meant steam used at pressures above or below this point. An engine which exhausted its steam into the open air—that is, at ordinary atmosphere pressure—was known as a high-pressure engine; an engine which exhausted into a condenser, where a partial vacuum was maintained, was called a low pressure engine. But these terms have lost their former significance. Absolute steam pressure is the total pressure computed from the zero of an absolute vacuum, as distinguished from relative pressure at sea-level. Ordinary steam-gauges indicate pressure above that of the atmosphere. To this must be added the pressure of the atmosphere in order to obtain the absolute steam pressure. The temperature of steam is sometimes expressed in degrees "absolute," meaning the number of degrees above "absolute zero", which is, on the Fahrenheit scale, —460°; that is, 460 below the zero mark on a Fahrenheit thermometer.

Saturated steam is steam at its greatest density and pressure at the particular temperature existing: that is, any increase in pressure or any lowering of temperature would cause condensation—a part of the steam would return to the condition of water. If saturated steam holds in suspension less than 3 per cent of unvaporized water, it is known as dry steam; if 3 per cent or more of water is present it is termed wet steam. Dry steam as it issues from a jet into the air is colorless; wet steam issues as a white cloud. The presence of free water in steam is highly objectionable. It represents a loss of heat without production of useful work, and to that extent reduces the efficiency of the boiler and increases the cost of the steam actually used. Further, it adds to the amount of water of condensation to be

cared for; increases the wear of valves and valve-seats; washes away lubrication; and, in the case of turbines, erodes the blades almost as if they had been subjected to a sandblast.

When a space is saturated with steam the pressure exerted is known as saturation pressure. If the content of a space which is saturated with steam be reduced, some of the steam is condensed to a liquid state, but the pressure remains the same. If the volume of the space be increased, provided that it contains sufficient liquid, more water evaporates and the pressure exerted by the water vapor soon attains the same value as before the change of volume. If the temperature of a space containing water, and its saturated vapor be raised, the saturation pressure of the vapor is increased; if on the other hand the temperature falls, some of the vapor is condensed, and the saturation pressure is less.

Superheated steam is saturated steam heated until it resembles a perfect gas. The superheating of steam is accomplished by "drying" it of the water vapor, or by relieving it of some of the pressure upon it. The former method is the one used in steam practice. The drying cannot be done while the steam is in contact with the water in the boiler, for any increase of heat applied to the latter goes to forming more saturated steam, the temperature remaining relatively the same—that is, according to the pressure. While saturated steam begins to condense at once upon loss of heat superheated steam retains its gaseous form until it has lost all its heat above 212°. This quality of steam makes it of great value in engines, the expansion in the cylinder being wholly gaseous, and without leaving any water of condensation—the source of the largest loss of efficiency in engines. The superheating of steam is commonly accomplished by passing it through a grid of pipes open to the fire. In ordinary engine practice the effect of superheated steam is secured by "wire-drawing" it—the term signifying the causing it to pass through a (relatively) very small opening. This is done on an engine by partly closing the throttle valve. The temperature remaining the same, the small fall in pressure results in superheating the steam allowed to pass through the valve.

Superheated steam has a lower thermal conductivity than saturated steam, and this quality reduces the leakage of heat to the cylinder walls by 12 per cent. The radiation from pipes carrying superheated steam is less, also. The fuel expense of superheating steam is not large: the amount of fuel required to raise steam to 100° of superheat—that is, to 312°, being an increase of only 5.69 per cent over that required to produce the saturated steam of 212°. The limit to which superheat may be added to water confined in a boiler is about 600°, equivalent to a pressure of 1,574 pounds per square inch. Above this point the proper lubrication of the cylinders of reciprocating engines, and the maintenance of packings of valves and condensing apparatus in normal condition is impracticable. The practical limit of safe pressure in modern boilers is 200 pounds per square inch, equivalent to a temperature of about 380°, or 168° of superheat. In the United States the range of superheat practice does not exceed 500

degrees, and there are few instances in which it exceeds 450°. In Europe, however, few plants are installed without superheaters, and the temperatures range from 600° for ordinary to 850° as the top limit. For these very high pressures specially built boilers are required, and the extra cost of such work offsets the advantages which may be gained. "Live steam" is steam which has performed no work, or rather which is available for the performance of work. Steam which has performed work is called exhaust steam. When a pound of water at 212° is turned into steam at 212°, 965.7 heat units are absorbed in the change of form. This energy reappears when the steam returns to the form of water. Herein lies the vast economic profit in the utilization of exhaust steam in the heating of feed water for the boiler, warming the shop, etc. Every pound of exhaust steam

the change from a liquid to a gaseous state takes place beneath the surface, the steam rising to the surface and escaping with ebullition.

The boiling point—that is, the temperature at which steam is formed, depends on the pressure under which it is generated. If the water is confined to a limited space, as in a boiler, if the pressure above it is relieved with an airpump, the boiling point will be lowered. If pressure is brought to bear on the water in the boiler, the boiling point is raised. This is, in effect, what happens in ordinary boiler practice: the pressure is increased by making more steam than there is room for in the boiler above the water. The steam being compressible, accumulates in a state of compression, and the boiler pressure rises, as shown by the steam-gauge. The following table gives the relations between pressure, volume and total heat of steam for temperatures between 32° F. and 428° F. During the first stage of heating, all the heat sensibly goes into increasing the internal energy of the fluid. This is represented in the last column of the table. During the second stage the heat taken in is known as latent heat of steam. The total heat of both stages is represented by the numbers in the fourth column of the table. The latent heat of the steam is determined by subtracting the heat content of the liquid from the heat content of the steam.

TABLE I.

Temperature in degrees Fahrenheit	Pressure per square inch in pounds	Volume per pound in cubic feet	Total heat content of steam	Heat content of water

FIG. 1.

has within itself the potency of 751,314.6 foot-pounds of heat energy, imparted to it by the fuel. If even but a part of this latent heat energy can be used, an equivalent amount of fuel is saved, or, what practically amounts to the same thing, so much of the fuel is used twice.

Vaporization.—When heat is applied to water, a point is reached at which the heat overcomes the cohesion and the pressure of the atmosphere, then the water passes into vapor. Evaporation takes place at the surface of the water. Its rapidity varies with the temperature and the pressure upon that surface. When a flask containing water (see Fig. 1) is placed over the flame of a lamp, the air dissolved in the water is first driven off, then as the temperature of the water rises, the liquid molecules in contact with the bottom of the flask become so hot that the heat is able to overcome their cohesion, the weight of the overlying water and the pressure of the atmosphere above the water. At this temperature

Dulong and Arago determined the tension of steam many years ago by means of the apparatus shown in Fig. 2.

In the figure (*k*) is a copper boiler, with a tube (*a*) containing a thermometer (*t*), which measures the temperature of the water, and its vapor. The tension of the steam is measured by a manometer (*m*). The steam passing through the tube (*c*) exerts a pressure on a column of water in the tube (*i*). This pressure is further transmitted to the mercury in the vessel (*d*), and thence to the manometer. By taking the manometer readings corresponding to each degree of the thermometer, a direct measurement of tension was obtained up to a pressure of 24 atmospheres, and from this on by calculation. The following is a table of results:

TABLE II.

Temperature	Number of atmospheres	Temperature	Number of atmospheres	Temperature	Number of atmospheres	Temperature	Number of atmospheres
100.0°	1	170.8°	8	198.8°	15	217.9°	22
112.2	1½	175.8	9	201.9	16	220.3	23
120.6	2	180.3	10	204.9	17	222.5	24
133.9	3	184.5	11	207.7	18	224.5	25
144.0	4	188.4	12	210.4	19	226.8	26
152.2	5	192.1	13	213.0	20	228.9	27
159.2	6	195.5	14	215.5	21	230.9	28
165.3	7						

Regnault, 14 years later, devised a method by which the vapor of water could be measured at temperatures above or below boiling point. By this method the following tensions were obtained for temperatures ranging from 10° below to 101° above zero, of the Centigrade scale.

TABLE III.

FIG. 2.

In the making of steam in boilers it is of the greatest importance that clean, soft water be used. The condensation of the salts in boiler water eventually reaches a point where they are deposited as scale on the inside of the plates and tubes, a condition in which much fuel is wasted. (See WATER SOFTENING).

The Energy of Steam.—Water has the greatest specific heat of any known substance, except hydrogen. By this we mean that more heat enters into it, in order to raise its temperature one degree, than into any other substance, with the one exception mentioned. Its stored energy as noted above is 965.7 thermal units per pound of water, Fahrenheit scale. It is easily condensed, giving out this energy. These facts, together with its universal and abundant presence in large quantities, have rendered steam, up to this time, a favorite means for the generation of mechanical power. The process of changing steam into mechanical power may be briefly outlined as follows: If we start with water at 32° F. and apply heat, the temperature of the water will rise one degree for each thermal unit, but expansion does not begin until 38° to 40° of temperature are reached. When 180½ units of heat have been absorbed the temperature of the water will be found to be 212° F. and its expansive force (into a vacuum) equal to 14.7 pounds to the square inch, or that of the atmosphere at sea-level. At this point the water is incapable of becoming any hotter under that pressure. The heat added, after that point is reached, is used in converting the water into steam, and 965.7 thermal units are required for each pound of water thus converted. This so-called latent heat is stored energy, to be given back again in mechanical work and heat, as the steam is condensed. If we enclose both water and steam in a boiler of suitable construction, and continue heating, part of the water will be vaporized, but being prevented by the confined space from expanding, it crowds the steam already enclosed into a smaller volume and the pressure upon the surface of the water is increased so that the heat now added increases temperature again. When we have added 1,188.6 total thermal units (including temperature and latent heat) the pressure or

energy of the steam will be equal to 101.6 pounds to the square inch and the temperature will have risen to 329° F. (See table I, columns 1, 2 and 4).

We have now to consider how this energy is transformed. When the steam in the cylinder of an engine performs work by pushing the piston against a resistance, that work robs the steam of a portion of its heat, hence the steam is condensed. Theoretically, it requires two and a half pounds of steam, saturated, to supply one horse power of work each hour; but practically, from 5 to 25 times that amount is required to pass through an engine in order to secure this result.

This is due to the loss of the energy of the steam, in giving up its heat to the walls of the cylinder, and to the immense portion of the steam which acts only as backing. In the best quadruple engines of to-day less than one-fifth of the energy of the steam is converted into actual work, and in the best non-condensing engines only one-tenth. The waste is enormous, but the abundance of the supply in part compensates for it.

According to the 1914 census of manufactures the number of steam engines and steam turbines employed in manufacturing in the United States was 137,176, and the total horse power developed was 15,681,688 or 69.5 per cent of all forms of power in the country. A large amount of steam is used, in addition to this, for heating purposes. Its value in this respect is due to its being able to carry more heat for a given weight than any other substance, and when it has given up its heat to drop out of the way, by condensation, and make way for a fresh supply. Steam is also used extensively in extracting processes. It is often injected directly into a liquid, bubbling through it and carrying over certain constituents to be released in the condensing chamber. In other cases, especially those of liquids boiling at a lower temperature than water, coils of steam pipes supply the mild degree of heat needed for a gentle distillation. Consult Goodenough, G. A., 'Properties of Steam and Ammonia' (New York 1915); Hausbrand, E., and Wright, A. C., 'Evaporating, Condensing and Cooling Apparatus' (London 1916); Holmes, U. T., 'Experimental Engineering' (Annapolis 1911).

RICHARD FERRIS,
Editorial Staff of The Americana.

STEAM-ENGINE, the apparatus by means of which the stored heat-energy of fuel, transferred to water and steam, is transformed into mechanical work. This transformation of thermal into dynamic energy, this thermodynamic change, requires for its successful and economical conduct special forms of mechanism and is subject to a variety of wastes of serious aggregate amount, even with the most perfect of modern engines. The series of processes in the train between the fuel and the point of application of the useful energy with statement of the corresponding wastes and efficiencies are as follows: it being understood that an efficiency is the quotient of useful result divided by outgo producing it, the two being

expressed in similar terms:— These efficiencies are those of

1. Combustion of fuel; ratio of heat set free to total heat latent in the fuel. This efficiency is usually not far from 90 per cent. Wastes due to incomplete combustion.
2. Heat-transfer from furnace to boiler; efficiency as a rule, about 75 per cent, as measured by heat stored in the steam supplied. Wastes occurring mainly at the chimney.
3. Heat-transfer from boiler to engine with loss by conduction and radiation, *en route*. Efficiency of operation about 90 per cent in small boilers and increasing to 95 or 98 per cent in large sizes.
4. Heat-transformation into work at the engine with wastes by defective thermodynamic change and rejection of heat at the lower limit by conduction and radiation within and without the cylinder, variable with size, with mean temperature of steam and other conditions. Efficiencies for the ideal case usually approximate 25 per cent with only thermodynamic wastes, and attain to 20 per cent with successful constructions in the real case; the wastes including the thermodynamic and inevitable losses and the partly controllable extra-thermodynamic wastes.
5. The transfer of mechanical energy from cylinder to point of application. The wastes occur by friction and usually amount to about 10 per cent, as a minimum in condensing, and to 5 per cent in non-condensing engines. Efficiency, 90 to 95 per cent.

The thermodynamic efficiency of the best steam-engines may be thus taken to be 25 per cent; the thermal efficiency at the engine, involving other wastes than thermodynamic, about 20 per cent; the total efficiency between steam-valve and fly-wheel about 18 per cent and the efficiency of engine and boiler combined not far from 14 per cent; while the total efficiency of engine, boiler and furnace, from coal-pile to engine-belt, may be about 12½ per cent. In common constructions these efficiencies are

Hero's Steam-turbine (120 B.C.).— A B, steam boiler; C D, supports; a, revolving globe; H K, nozzles.

much reduced and in many cases may be divided, by from two to four, the demand for fuel of good quality ranging from about one pound or half a kilogram in the best work to several times that amount per horse-power-hour, and for steam from 10 pounds, about four and a half kilograms, to a multiple of that quantity. In some instances, as with many small boiler feed-pumps, 10 or even 20 times the minimum figure just given are reached, the wastes becoming enormous and the utilized energy of the fuel insignificant.

The "ideal case" is understood to be that purely thermodynamic operation which illustrates the conversion of thermal into dynamic energy where no other energies than thermal and dynamic are concerned, and where the change is effected in a machine which is not subject to wastes by conduction or radiation; an apparatus composed of perfectly non-conducting materials and perfectly constructed. In the "real case," the materials of construction are necessarily good conductors and good

radiators of heat, and the wastes by conduction and radiation are often supplemented by leakage of steam as well as of heat. In the real case, the details of construction, adjustment and operation affect very greatly the resultant efficiency and the commercial rating of

Savery's Engine (1702).—L, boiler; G, feed-vessel; PP, forcing vessels; S, rising main; T, suction.

the engine. The study of the steam-engine thus comprehends the ideal, the purely thermodynamic, case and the real case with its various wastes, thermodynamic and extra-thermodynamic, as well as an investigation of the principles and practice in the design and construction of the real engine.

Newcomen's Engine (1705).—B, boiler; a, steam-cylinder; s r, piston and rod; K, pump rod.

Engines.—The power of steam and the employment of that fluid in various sorts of engines have been familiar to mankind from an unknown and possibly prehistoric period. The earliest known record is that of Hero, who, in his 'Pneumatica' of which the manuscript was produced at Alexandria, about 120 B.C., de-

scribed a steam-turbine and several forms of steam-fountains and steam-boilers. So far as known, none of them had any useful application and they were simply toys or impracticable schemes. It is unknown, in fact, whether any of them were constructed; although the drawings appear in some cases to be those of actual constructions.

Through the later centuries, up to the 17th, but little progress was made either in the acquirement of a knowledge of the properties of steam or in its application to useful purposes. Some forms of "æolipile," furnished a steam-jet for improving the draft of the chimney, apparatus for turning the spit and even more ambitious uses were either attempted or suggested; but, until Da Porta's treatise on pneumatics appeared in 1601, in which a steam-fountain was described, and the description in 1629 of an impulse steam-turbine, by Branca, no development took place of any real importance.

Watt's Engine (1774).—a, cylinder; b, piston; x, rod; y, beam; i, j, air-pump and condenser; m, valve-gear.

It was not until the second Marquis of Worcester, Edward Somerset, constructed a steam-fountain (1650) and employed it in raising water from the moat to the top of the tower of Raglan Castle, and later erected another for similar purposes at Vauxhall, that the story of the evolution of the steam-engine really begins. Meantime the scientific men of the later centuries were acquiring some exact knowledge of the nature of steam, earlier confounded with other gases, and some familiarity with its latent powers.

Steam power first became an acknowledged industrial agent and useful as a prime mover when Savery, at the beginning of the 18th century (1698), made Worcester's steam-fountain practically applicable to the drainage of mines and the elevation of water for water-supply generally. This apparatus, which could not be properly called an engine, consisted of a pair of cylindrical or ellipsoidal "forcing ves-

sels" which were alternately filled with water, by the production of a vacuum within the vessel, and emptied by the introduction of high-pressure steam from an adjacent boiler; the one being emptied while the other was filling and vice-versa. This apparatus, introduced by Savery, improved and further made known by Desaguliers and by Smeaton, was known and in use before the year 1775 throughout the world where mining at considerable depths and in presence of water was carried on. The steam-fountain is still in use and is known as the "pulsometer."

Watt's Double-acting Engine (1784).— C, cylinder; b, beam; O, connecting rod; Q s, governor and valve.

Newcomen's steam-engine, the first steam-engine properly so termed, the first which consisted of a train of mechanism as distinguished from the Hero steam-fountain, which was a piece of apparatus without moving parts, was patented in 1705. It consisted of a steam-cylinder and piston, actuating a beam, above from the opposite end of which was pendant the pump-rod operating the pumps in the shaft of the mine; it was always used as a steam pumping engine. Thomas Newcomen and his partner, John Calley, are thus to be credited with the invention and introduction of the modern steam-engine with all its essential elements as a pumping engine. It was the improvement of this engine by the addition of various valuable devices which gave James Watt his fame and fortune.

This earliest type was a condensing engine in which condensation was effected by means of a jet of water directed into the steam cylinder when the pressure on the under side of the piston was to be removed. The upper side was open to the air, there being no upper cylinder-head. The engine was thus operated by the atmospheric pressure, steam being held at about atmospheric pressure and only employed to secure a vacuum below the piston. The pressure of the atmosphere depressing the piston, the pump-rod on the opposite end of the beam was raised and the pump filled. With

the fall of the pump-rod the water was forced out of the pump and raised to the upper level. The weight on the outer end of the beam always overbalanced the weight of the piston and attachments sufficiently to do the required work. This type of engine remained in use for a century, and old engines of Newcomen's time are still in existence. The type became known, later, as the Cornish engine, Watt's improvements having been meantime added. After Newcomen's death, the machine was improved in details by Desaguliers and by Smeaton, who considerably increased its economy by attaching wood to the piston and cylinder-head to prevent what has been called "cylinder condensation" by action of alternately heated and cooled metal in contact with the steam. This was probably the first recognition in construction of this important phenomenon.

The valves of this engine were at first worked by hand; but a boy, Humphrey Potter, is credited with having devised an automatic system, which, later in 1718, carefully designed and constructed in a workmanlike manner by Henry Beighton, a well-known engineer of that period, became the first automatic valve-motion.

James Watt, introducing the needed improvements in the Newcomen engine, finally produced the modern types of "reciprocating" steam-engine. His first great improvement was the separate condenser, which permitted condensation to be effected without the introduction of water into the working cylinder and thus reduced very greatly the waste of steam by initial condensation. Watt first enunciated the principle: "Keep the cylinder, if possible, as hot as the steam that enters it." The first step was this of removing the primary cause of refrigeration. The next was to surround the cylinder with a chamber containing steam at boiler pressure; thus introducing his second great invention, the "steam-jacket." He next covered the upper end of the cylinder, excluding the cold air and supplying the place of the atmosphere and its pressure on the upper side of the piston by steam from the boiler, completing his scheme of keeping the cylinder as far as was practicable as hot as the entering steam.

The "double-acting engine" constituted the next and an easy step. With steam admitted at both ends of the cylinder, it was immediately evident that each might be utilized, alternately, in the performance of work and Watt soon adjusted his valve-gear and connections in such manner as to permit this alternation and produce a push and a pull on the piston-rod. This compelled a rigid connection between the piston and overhead beam, on the one end, and between the outer end of the beam and its work, now become that of rotating a shaft with crank and fly-wheel. Thus one improvement led to another and Watt's steam-engine ultimately became capable of supplying power to every imaginable kind of machine or work. The single-acting engine was, for many years after Watt's death, used in raising water and the double-acting engine continues to turn the shaft of mill, locomotive, steamship and factory.

Watt invented and introduced many accessory inventions and devices, as the attachment of the governor—already a well-known apparatus—the steam-engine "indicator," the ex-

pansion of steam, the compound engine, the non-condensing engine, practically all that distinguishes the modern engine from that of Newcomen. These improvements raised the "duty" of the pumping engine, in the course of 25 years, from about 7,000,000 foot-pounds to 30,000,000, and, in the latest forms of Cornish engines, about 1850, to twice the last figure or more, reducing cost of steam-power enormously, and at the same time adapting the steam-engine to every requirement in the industries, giving to the world, in fact, its contemporary civilization. This cost in coal per horse-power-time is reduced from the 35 pounds of Smeaton's time to one pound, as a minimum to-day, and the work of the world is performed by steam-engines, mainly, probably amounting to 150,000,000 horse power and equivalent to the working power of several times the population of the globe, if employed in manual labor.

At the commencement of the 19th century, Trevethick and other able mechanics and inventors were seeking to construct locomotives, and complete success was achieved by George Stephenson in engines built from 1814 to 1833. The steamboat had been suggested by numerous writers and engineers, and, after many attempts, was made a practical success by John Fitch in the United States about 1785, by John Stevens in 1804-09 and commercially by Fulton, 1807-15. In Great Britain, after many early failures, Miller and Symmington and Bell, step by step, attained permanent success and by 1830, the date of the first transatlantic steamship voyages, those of the *Cirius* and the *Great Western*, all civilized countries were employing the steamboat. See STEAM VESSELS.

Meanwhile the elements of economy became recognized and steam-pressures rose from the two to seven pounds above the atmosphere of Watt's time to 25 or 30, about 1850, and to 100 and upward to occasionally 200 at the end of the 19th century; the ratio of expansion of the steam increasing in similar ratio. The speeds of engine-piston also gradually increased from about 100 feet per minute, at the beginning, to 600 and often to 1,000 at its end. The weights of engine and sizes for the usual powers meantime fell from 1,000 pounds or more per horse power developed at the time of Watt, 500 about 1850 and to 250 in 1900 where weights were comparatively unimportant and, in special cases, where weight and volume required to be reduced to the smallest possible figures, as for torpedo-boats, to a fourth or a fifth the last-named quantity.

The compound, the triple and the quadruple expansion engine have largely displaced the simple engine of Watt; the first of these types having been introduced in Watt's time by Hornblower, Woolf and Falk and the second by Kirk about 1874; while the last-mentioned became standard with the rise of steam-pressures to about 15 atmospheres, about 1890. These complications are mainly the outcome of the endeavor to follow Watt in repressing the waste by cylinder condensation, reducing the proportion of heat-absorbing surface and the temperature-head producing flow of heat into the metal of the cylinder. Incidentally, the multiple cylinder engine gives a steadier rotation of the crank-shaft and a smoother action of the steam than the simple engine, and also reduces weight

by lessening the maximum load upon the working parts, the range of pressure in each cylinder being reduced with this reduction of temperature-range.

This steady progression from the days of Watt to the present finally culminated in a retrogression to the simple form of the Hero engine, the steam-turbine, in which all the complication of the Watt-Newcomen engine is done away with and but one moving part performs every essential office, apart from condensation, and yet secures, in its best constructions, the economical results of the whole series of changes distinguishing the 19th century, with the added gain of reduced volume, weight and cost, both initial and operative. The turbine promises thus to provide power with maximum ultimate result in financial efficiency. Meantime, the gas-engine, after a similar period of development, is now rivaling the reciprocating steam-engine in many of its fields. The best steam-engines of both the standard types and the gas-engine are now capable of deriving large powers from substantially the same quantity of energy potential in fuel.

The *Structure of the Steam-engine* differs in detail according to place and purpose. The familiar forms may be thus classed: A primary classification as *condensing* and *non-condensing* distinguishes engines by their utilization or non-utilization of the vacuum. In the former class, condensation may be effected by surface or by jet-condensation; this distinction indicating a subordinate method of identification of a variation within the type. The usual classifications are based upon the essential features of structure, and these are ordinarily as follows:

1. According to the number of cylinders:
 - (1) Single cylinder, simple engines.
 - (2) Multiple-cylinder engines, "compound," etc.
2. With reference to the construction of cylinders:
 - (1) Fixed cylinder.
 - (2) Movable cylinder.

In the first case, the engines are:

 - (a) Vertical.
 - (b) Horizontal.
 - (c) Inclined.

In the second case, they are:

 - (a) Oscillating, vibrating, etc.
 - (b) Rotary, steam-turbines.
3. With reference to the action of the steam:
 - (1) Single-acting.
 - (2) Double-acting.
4. With reference to the transmission of the steam power:
 - (1) Direct-acting.
 - (2) Indirect-acting.

And in the latter case either —

 - (a) With balance lever, or beam.
 - (b) Without lever or working beam, geared, etc.

The essential details of these engines are usually the same in all the forms in which the individual piece is found. A rod or a crank, a shaft or a valve, will commonly be found to have assumed a standard form, and the difference in engines is largely a difference in grouping. Since Watt, but few advances have been made in real invention, and the progress observed has been mainly one of refinement and adaptation. Frederick E. Sickels introduced a successful form of "drop cut-off"; Corliss, Greene and others invented improved valve-gears embodying the same general principles, and Potter and Allen, and others, successfully established the "high-speed" engine as a motor where rapid rotation of the prime mover facilitated transmission of power, as with electric generators and in rolling mills.

Similarly, the locomotive proposed by a number of earlier inventors, particularly by Trevethick, who constructed several, was successfully brought into use by George Stephenson and, to-day, in its many forms and uses, the engine in its essential details and distinguishing features is that of Stephenson, refined and adapted to high and to low speeds, to heavy and to light loads. A very noticeable feature of the later engines is the forward "truck" or "bogie," devised by John B. Jervis, which, by permitting the forward wheels to swivel and the engine to rock upon the truck, accommodates the locomotive to sharp curves and irregular track.

In marine construction, a similar adaptation of the form and proportions of the engine to the special purpose in view gives rise to the types employed with side-wheel and screw, high powers and low, to the essential requirements in lightness and small bulk of torpedo-boat practice and the needs of transatlantic navigation and of that of the rivers of the United States. The substitution of surface condensation for condensation by the jet has been compelled in sea-going ships by the use of high-pressure steam and the impracticability of using sea-water in the boilers. The latter forms of engine are thus refinements and adaptations of the earlier.

Meantime, in all directions, the steam-engine has come to be utilized in the production of very large powers, and its construction in very large units is found to be very frequently economically desirable. Stationary engines for mills, and especially for large power-stations supplying the energy applied in electric lighting or power distribution for electric railways, are built in sizes ranging from a few hundred horse power up to 13,000 horse power, and sometimes grouped into systems rating as high as 100,000. Marine engines are also constructed in these large sizes and powers, and as high as 70,000 horse power may be used for the latest and largest transatlantic steamers, as in the *Mauretania*. The locomotive, in the time of Stephenson weighing, in the case of his first successful machines, four to six tons is now built of nearly 120 tons weight and capable of hauling loads of 30,000 tons at good speeds, on level rails. The steam pumping engine of the time of Newcomen and Watt had a capacity of a few hundred thousand gallons per day; it is now furnished in sizes up to 75,000,000 gallons per day for reciprocating engines and up to 320,000,000 for rotary engines, while its duty has risen from the comparatively insignificant figures of the times of the inventors to 150,000,000 and even 180,000,000 foot-pounds per hundred pounds of fuel. The steam-turbine, for all these uses, may now be obtained in as large powers as the reciprocating engine and with substantially the same guaranteed duty. Its relatively high speed of rotation, ranging from 600 to 3,000 in the largest sizes, to 30,000 in the small, and its smooth rotation, make its use distinctively advantageous in electric services and its small weight and volume are peculiarly helpful to the marine engineer and naval constructor.

The Thermodynamics of the Steam-engine, the science of its ideal case, involves the fundamental principles of Energetics and in particular the laws governing the transformation of

energy from the form of heat to that of mechanical energy and vice-versa. An all-comprehending law, of which the laws of Energetics are in fact corollaries, the law of Existence, or of whether matter or force or their resultant, energy, and in whatever form, is indestructible by finite power.

Matter may change its form and its chemical composition by rearrangement of its molecules or of its elementary atoms, but it cannot be destroyed; forces inhere and are persistent as characteristics of all matter and cannot be separated therefrom; energy, like matter, is constant in its total quantity in the universe and may be transferred and transformed, but cannot be extinguished. Transformation of energy, as of thermal into dynamic or mechanical, is simply the change of the kind of mass affected and consequent alteration of the kind of motion due to its action. A shot from a gun, stopped in its rapid flight by impact on the target, if not fractured, will exchange the thousands of foot-tons of mechanical energy sustaining its flight for precisely the same quantity of molecular motion and energy. Similarly, were a shot heated to a high temperature and then were all its molecules by some conceivable process of steering each into its path, made to take up simultaneously a definite rectilinear motion, it would become absolutely cold and would fly out into space with a dynamic mass-energy precisely equal and, in fact, with the identical energy at first displayed as molecular. The heat-engine is a device for bringing about such a change for industrial purposes.

The laws of energetics, as usually enunciated, are:

1. *The Law of Persistence, or of Conservation of Energy*, namely: Existing energy can never be annihilated; and the total energy, actual and potential, of any isolated system can never change.

This is evidently a corollary of that grander law, asserting the indestructibility of all the work of creation, which has already been enunciated.

2. *The Law of Dissipation, or of Degradation of Energy*, namely: All energy tends to diffuse itself throughout space, with a continual loss of intensity, with what seems, now, to be the inevitable result of complete and uniform dispersion throughout the universe, and consequently of entire loss of availability.

It is only by differences in the intensity of energy, and the consequent tendency to forcible dispersion, that it is possible to make it available in the production of work.

3. *The Law of Transformation of Energy*, namely: Energy may be transformed from one condition to another, or from any one kind or state to any other; changing from mass-energy to molecular energy of any kind, or from one form of molecular energy to another, with a definite quantivalence.

Thermodynamics, being a restricted energetic, in which only two energies, thermal and dynamic, are comprehended, its laws are, fundamentally, identical with the preceding and the enunciation just adopted is entirely accurate in this restricted science.

The Laws of Thermodynamics, in the special forms considered best for the purposes of the thermodynamist, are corollaries of the laws of energetics and of Newton's laws, which are a different method of expression of the same fundamental principles. They are usually stated thus:

1. *Thermal and Mechanical Energy are mutually interconvertible in the proportion of one British Thermal Unit for each 778 foot-pounds, or of one calorie for each 427 kilogrammetres of energy or of work.*

The mechanical equivalent of heat is the specific heat of water at its temperature of maximum density expressed in dynamic units, as foot-pounds or kilogrammetres.

The value of the mechanical equivalent of heat has been taken as first adopted by Joule, although recent and most carefully conducted investigations indicate a value higher by perhaps 1 per cent, to be more accurate. Many existing tables, and much work done in this field to date, have, however, been based upon Joule's figure, 772 foot-pounds, 423 kilogrammetres. The figure, above given, 778 or 427, is now, however, generally accepted.

2. The total of any single effect of any given quantity of heat acting in any thermodynamic operation is proportional to the total amount of heat-energy so acting.

This principle is substantially that first accepted by Rankine as the second law. Actually energy of vibration is understood.

Thus, of the whole quantity of heat passing from the heater to the working substance, one part is always transmuted into mechanical work, or energy; while the remainder goes to the refrigerator, and the ratio of the one quantity to the other is perfectly definite.

Professor Wood expresses this law thus:

"If all the heat absorbed be at one temperature, and that rejected be at one lower temperature, then will the heat which is transmuted into work be to the entire heat absorbed in the same ratio as the difference between the absolute temperatures of source and refrigerator is to the absolute temperature of the source."

The second law finds important application simply in enabling us to ascertain the total quantity of work, external and internal, required to produce changes of volume and energy in fluids, like the vapors, in which we cannot measure directly the internal forces and internal work.

If the change of sensible heat be called dS , that of "latent" heat, dL , and of external work, dU , then the first law of thermodynamics is expressed by the equations:

$$dH = dS + dL + dU, \dots \dots \dots (A)$$

and

$$dH = dS + dW, \dots \dots \dots (B)$$

$$dH = dE + dU, \dots \dots \dots (C)$$

where, in the last two expressions, $dE = dS + dL$, and is the variation of energy, actual and potential; while $dW = dL + dU$, and is the total work done, externally and internally. These are primary and general equations.

The quantity E is often called the intrinsic energy of the substance; L is evidently a potential energy; while S is a form of molecular kinetic, or actual, energy, which may sometimes be regarded as also in a sense potential.

The above are completely general expressions of the general fundamental equation of thermodynamics.

Internal work or energy, positive or negative, is the work performed in changing the relative distances between molecules, atoms or corpuscles, or in causing variation of their relative velocities, and within the mass and out of reach of the human senses. In the fundamental equation, it is measured by dL .

External work is that performed by mass or molecule, by atom or corpuscle against outside resistances, as where steam expands, doing work upon a piston. As indicated by the above laws, it must do so by surrendering an equivalent quantity of heat-energy. This is dW .

Heat-energy, thermal or dynamic, is of the same nature and may be measured in either thermal or dynamic units, foot-pounds and kilogrammetres, or in British or metric thermal units or "calories." One *B. T. U.*, expressed in thermal units, is 778 foot-pounds expressed in dynamic units; one metric unit, the calorie, is 3.96832 times as great as the British, or the *B. T. U.* is 0.251996 of the metric unit. The engineer often conducts his thermodynamic investigations in dynamic terms; the physicist and the chemist employ the thermal; the one often uses British, the other always adopts the metric. Where work is performed by an expanding fluid upon a moving piston, the total work,

$$U = (p_e + p_i)as;$$

where a is the piston-area, and s is the space traversed by the piston; mean pressures corresponding to the external and the internal work being p_e and p_i while $as = v$, the volume traversed.

The Perfect Gas is a fluid within which no

internal work is done with varying volumes and which may be defined by the equations, $pv = aT$; $pv/T = a$. In thermodynamic equations, the perfect gas has zero values of internal energy and work. T is absolute temperature, p and v the pressures and volumes at that temperature of unit mass.

Corliss Engine Valve-motion (1850).

Vapors are fluids in which the internal energy and work may be large, both absolutely and relatively, with changing volumes. Internal cohesive forces are often not only sensible but very great, the internal latent heat, which simply measures the internal work when expanding water into vapor of one atmosphere pressure, as an example, is the equipment of the work of elevation of the weight affected to a height of about 150 miles. These forces, however, as with the gases, do not prevent the free movement of molecules in any direction and to any extent; nor do they fix the volume and density of the substance.

Liquids are fluids in which the action of internal molecular forces gives stability of volume, but not of form, and the energies, internal and external, are thus limited to comparatively small ranges and to comparatively small values; while range and values are often enormously great when the liquid becomes vaporous, notwithstanding rapid diminution of molecular attractions.

Solids have stability, both of volume and of form; the ranges of internal forces and of energies are still more restricted than with liquids and their extent of action and their values are still less than in liquids. By accession of heat, all solids become at some definite point liquid, liquids become vapors and vapors, when "superheated," become gases. It is to be noted that, whenever a substance, of whatever class, alternately expands and contracts through a fixed range of volume, whatever its temperature or the pressure, precisely the same amount of internal energy is lost and gained by variation of volume against or with the constant effort of the internal forces.

Cycle is, thermodynamically, an operation in which a working substance passes through a series of changes of pressure, volume and temperature resulting in the final return of the substance to its initial physical state. In this

operation, it is evident that the net change of internal energy is zero. This process is illustrated in heat-engines in which the working substance is confined within the working chamber and therein passes through repeated cycles with repetition of the kinematic cycle of the machine itself. Obviously, also, where a working fluid traverses a cycle, the presence or the absence of the quantity of internal energy becomes a matter of no importance when we seek only to determine the quantity of permanent thermodynamic transformation. The magnitude and effect of internal forces and energies have no influence upon the efficiency of transformation; but they have importance as affecting the relations of pressure, volume and temperature and the magnitude of the working cylinder and of the heat-engine itself. In the highest boiler pressures now usual, these forces are about 10 times the gauge pressure. At atmospheric external pressure, they amount to 13 atmospheres. These pressures cannot be measured by any gauge, but may be readily computed with precision from easily ascertainable data; they are

Greene Engine (1855).

perfectly well known, as are the specific volumes of the fluid, which are very difficult, but not impossible, of direct measurement.

The gas-engine has the advantage in comparison with the steam-engine, in its higher available temperature range and consequent higher thermodynamic efficiency.

The exact treatment of the thermodynamics of the steam-engine requires the use of the higher mathematics, but the general principles have been given and the following will permit its applications to be understood:

A steam-engine is a thermodynamic system in which only thermal and dynamic energies are present and operative. Its action is to transform as large a proportion as possible of the heat supplied it into mechanical power and work. Each pound of steam from the boiler

usually brings over the equivalent of about 0.4 horse-power-hour and each horse-power-hour is the ideal equivalent of the heat-content of about 2.3 pounds, a kilogram, nearly, of boiler steam. Of this heat, a part, which is precisely measured by the area of the indicator diagram, is converted into useful work and an "efficiency" is attained measured by the ratio of the useful to the supplied energy in common units. Thus: where 23 pounds of steam per hour are demanded per horse power developed, in the case assumed, the efficiency is 10 per cent; the heat supplied being that furnished from the fuel and measured by the difference between the "total heat" of the feed-water at condenser temperature and that of the steam in the boiler.

The nine-tenths which fails of utilization is composed of a variety of wastes, including the thermodynamic, that portion of the heat reaching the steam-cylinder and actually acting upon the piston which is not converted into indicated work, the waste by conduction and radiation externally and the waste by the transfer of heat between the metal of the cylinder and the working fluid. These quantities in a good example may be taken as follows, the friction wastes of the machine itself being included:

Available heat-energy from the boiler.....100	Thermodynamic wastes.....	70
	Internal thermal loss.....	10
	External waste.....	5
	Friction.....	2
	Useful work.....	13
		100

This corresponds, for the ideal case, to an efficiency of 0.20, nearly.

The external waste of the steam-engine is usually considered to be covered by an allowance of about one *B. T. U.* per square foot per hour per degree range of temperature, Fahrenheit, or about three calories per square metre, although, on exposed metal having a rough surface, it may attain two to three times these figures. The exterior of the cylinder is commonly lagged and the heads, if not thus covered, are polished, thus minimizing the waste. The total waste, on even small engines, has been found capable of being reduced to less than 3.5 per cent, total, inclusive of engine and boiler, by the use of good non-conducting coverings. This loss is often quite unimportant on large engines.

The internal wastes are produced by heat-exchanges between metal and steam, at induction and eduction; the steam giving heat to the metal at its entrance into the cylinder and robbing the metal at exhaust, thus transferring heat often in large quantities from the steam to the exhaust side, very much as leakage carries the steam itself with its charge of heat. The effect on efficiency is precisely that of leakage. In this action, the cylinder-heads and the sides of the piston, being exposed to the widest range of temperature and for the longest periods, are most fruitful of waste; the cylinder, proper, and especially its middle portion, wastes least. The total loss is a function of the temperature range, the time of exposure to transfer, and the quality of steam, and of the ratio of expansion which measures rudely the quantity of steam per unit weight of metal. In any one engine it may be stated, as a rough approximation, that the condensation is a constant quantity at all expansions. It may be treated as either a constant leakage or as a

constant loss of work measurable by an equivalent back-pressure. A common value of this leakage may be taken, in pounds, as not far from 0.02 *B. T. U.*, per square foot of surface exposed at cut-off, per minute per Fahrenheit degree of temperature-range. As a fraction of the steam supplied, it is approximately proportional in any given engine to the square root of the ratio of expansion. With various types of engine, it ranges from 25 or 30 per cent, with simple engines of moderate size to 10 per cent, in multiple-cylinder engines of modern construction as a minimum. In steam pumps and very small engines, it may amount to more than the whole amount of steam taken in, for thermodynamic action. These machines, demanding 100, and even sometimes 150 or more pounds of steam per horse power hour, waste three-fourths or more by "leakage" of heat. The "record-breaking" engines of large size and superior design demand as little as 10 to 12 pounds, approximating 200 *B. T. U.* per horse power hour.

The velocity of heat-exchange in this manner is many times greater than in transfers across the boiler heating surfaces. It is the most rapid known form of condensation of steam, and is often 10 times as rapid as the production of steam in the boiler supplying it.

The conditions of maximum efficiency are mainly two: the reduction to the practicable minimum of the thermodynamic waste by increasing in all possible ways the area of the indicator diagram per unit of steam supplied, and by minimizing the wastes of heat between boiler and engine-piston. The first includes the increase of the initial pressure, with decrease of back-pressure and adjustment of the ratio of expansion of the steam to the range thus secured; the second involves reduction of conduction and radiation by use of suitable non-conducting coverings of heated surfaces, protection from cooling influences and reducing "cylinder condensation" by drying and superheating the steam, by increasing the speed of engine and by diminishing the heat-exchanges between metal and steam by fine finish of surfaces, and, where practicable, by interposition of non-conducting material, as was done by Smeaton and attempted by later inventors.

"Mechanical efficiency," the ratio of work transmitted from the piston to the point of useful application, ranges from 95 per cent in direct-acting engines as a maximum, to 85 per cent with the older non-condensing engines. It is made a maximum and friction reduced to a minimum by careful design, and especially by securing constant, complete and free lubrication; usually, in the best cases, by a circulatory flow of oil, flooding the bearings and returned by pumps to the source, through a filter, to be again distributed to the rubbing surfaces of the engine. The lost work is the less, as the pressures are higher within limits determined by the nature of the materials, as the lubricant is better adapted to its intended purpose, and as the flow is more liberal where reaching the rubbing parts. The highest values of the coefficient of friction are often 10 and sometimes 20 times the lowest and the careful attention of the engineer to this detail is always well compensated.

The ultimate limit of economy in operation, with any class of engine, is fixed by financial

considerations, and the principle involved in determining the limit may be thus expressed:

That engine is most perfectly adapted to its place and purpose of which the type is such that no practicable substitution will permit the supply of the demanded power at lower total operative costs, including interest on first cost, a sinking fund to provide for replacement at the end of its period of use and annual operating expense; and that size of engine is on the whole best, variation from which in the direction of either increased or lessened size will increase that total expense of operation. In the latter case, the gain by reduction of size will be more than compensated by the loss due to its reduced efficiency. The best engine is that which will give largest returns on the capital invested, adding most effectively during its life to the dividends obtainable from the "plant" of which it forms a part.

The adjustment of the ratio of expansion of the steam to the requirements of maximum efficiency is the vital problem of the designing engineer and the purchaser of the engine. In the ideal case of the purely thermodynamic machine, this ratio is that of the initial to the back-pressure, very nearly, and the terminal pressure on the expansion-line should coincide with the back-pressure. For maximum economy of fuel, this expansion ratio should be reduced in proportion, closely, to the loss by heat-wastes between boiler and piston. For maximum efficiency from the financial point of view, a still further reduction is required in proportion to the relation of the operating costs apart from those of steammaking to those of engine-operation proper. Thus, in the thermodynamic case, with initial and final pressures, respectively, 10 atmospheres and one, the ratio is reduced, often from about 10 to seven or eight by initial condensation and minor wastes, and to six by adjustment to that value, departure from which, in either direction, would increase total costs of the horse-power-hour.

With condensing engines, the ideal ratio might be 40 or 50, while the ratio for maximum duty would be not above 20, and the best ratio, from the point of view of the treasurer, might be not above 12 or 15. The accuracy with which the designing and constructing engineer determines the adjustment for maximum financial efficiency is a measure of his ability and skill and a gauge of his success in solving his problem. With each standard construction, experience usually enables the engineer to satisfactorily determine the proper solution of this problem.

The case of the steam-turbine exhibits here one of its essential peculiarities. The ratio of expansion is fixed by the conditions of its design, construction and operation and is necessarily the ratio of initial to back-pressure if properly constructed. The maximum efficiency of the turbine is obtained at its maximum power and it possesses the same inherent inflexibility as the hydraulic turbine, if of other than the "partial" class, in which latter case power is adjusted to load by varying the number of nozzles or supply-passages in action. It has the same possibilities of adaptation as has the hydraulic with, further, available recourse to intermittent supply, as with the Parsons turbine, a plan unavailable with the hydraulic machine,

as an element of regulation. The steam-turbine, also, is not subject to internal condensation as all its elements, when in steady operation, maintain a constant temperature. Its economic theory is thus greatly simplified. Its financial theory simply dictates the construction of a light, rapidly moving vane and a minimum cost of application to its work, to operation and to maintenance, as a total.

Essential Parts of the Steam-Engine.—

The steam-engine consists necessarily of two parts—the engine proper, in which the expansive force of steam is expended and the generator or boiler, in which the energy derived from a burning fuel is transferred to water. (The steam generator or boiler is fully dealt with in the article *BOILER*). The engine proper is made up of several parts of which the chief is a cylinder in which a piston is moved by the expansive force of the steam generated in the boiler. The boiler is connected to the cylinder by means of the steam pipe, in which is a stop valve, also the throttle valve or regulator, for adjusting the opening for the admission of steam to the cylinder, which in some engines is regulated by hand, and in others by a governor. The steam pipe contains sometimes also the cut-off valve or expansion valve, for cutting off the admission of the steam to the cylinder at any required period of each stroke of the piston, leaving the remainder of the stroke to be performed by the expansion of the steam already admitted to the cylinder. The cylinder, the heart of the steam engine, may be single or double acting. In a single-acting engine, the piston is forced in one direction by the pressure of the steam, and made to return in the opposite direction when the steam is discharged by the action of a weight or counterpoise. In a double-acting cylinder, the piston is forced in either direction by the pressure of the steam which is admitted and discharged at either end of the cylinder alternately. The admission and discharge of the steam take place through openings near the ends of the cylinder, called ports (see illustration), connected with

pipe is placed in the centre of the chimney, so that the successive blasts of steam discharged from it augment the draught of air through the furnace, and cause the combustion of the fuel to be more or less rapid, according as the engine is performing more or less work. The cylinder cover has in it a stuffing box for the passage of the piston rod; in large engines there are sometimes more than one piston rod and stuffing box, and sometimes a tubular piston rod, called a trunk. The cylinder cover is also provided with a grease cup to facilitate the lubrication of the cylinder and piston rod. In many large engines, there is a spring safety valve, called an escape valve, at each end of the cylinder; the chief use of which is to discharge water which may condense in the cylinder, or be carried over in the liquid state from the boiler, by what is called priming. To prevent condensation in the cylinder, it is sometimes enclosed in a casing, called a jacket, the intermediate space being filled with hot steam from the boiler, or hot air from a flue. Outside the jacket, to prevent loss of heat externally, there is a covering of felt and wood or other insulation. Double cylinder engines have two cylinders; the steam being admitted from the boiler into the first cylinder and then filling the second by expansion from the first. The ordinary condenser is a steam and airtight vessel of any convenient shape, in which the steam discharged from the cylinder is liquefied by a constant shower of cold water from the rose-headed injection valve.

In land engines the injection water comes from a tank called the cold well, surrounding the condenser, and supplied by the cold water pump; in marine engines, it comes directly from the sea. In the surface condenser the steam is liquefied by being passed through tubes or other narrow passages surrounded by currents of cold water or cold air. The condenser is provided with blow-through valves, communicating with the cylinder, usually shut, but capable of being occasionally opened, and with a snifting valve opening outwards to the atmosphere; through these valves steam can be blown to expel air from the cylinder and condenser before the engine is set to work. The condenser has also a vacuum gauge, to show how much the pressure in it falls below that of the atmosphere. The water, the small portion of steam which remains uncondensed, and the air which may be mixed with it, are sucked from the condenser by the air pump, and discharged into the hot well, a tank from which the feed pump draws the supply of water from the boiler. The surplus water of the hot well in land engines is discharged into a tank there to cool and form a store for the cold well; in marine engines, it is ejected into the sea.

In all, except certain peculiar classes of engines, there is a parallel motion for guiding the head of the piston rod to move in a straight line, consisting either simply of straight cheeks or guides, or of a combination of levers and linkwork, invented by Watt, and more or less modified by others. The special classes of engines above referred to are—first, trunk engines, where the stuffing box is the guide; secondly, oscillating engines, in which the head of the piston rod is directly connected with the crank, and the cylinder oscillates on trun-

Slide valve, ports, piston and seat of an ordinary steam-engine. In the position shown, steam is entering from the steam-space S through the port A to the space Q; steam in R is exhausting through port B to E.

passages called nozzles, which are opened and closed by induction and eduction valves. Sometimes the induction and eduction valves are combined in one valve, called a slide valve. The valves are contained in the valve chest. In non-condensing engines (conventionally called high pressure engines), the waste steam discharged from the cylinder escapes into the atmosphere through the blast pipe; in locomotive engines, as well as some others, the blast

nions; thirdly, disc engines in which the functions of a cylinder are performed by a vessel of the figure of a spherical zone and those of a piston by a disc having a motion in that zone, and fourthly, rotary engines, in which the piston revolves round an axis. In single-acting engines for pumping water, the pump rods are worked either by direct connection with the piston rod, or through the intervention of a beam. In double-acting engines, the power is communicated to a revolving shaft, driven by means of a crank and connecting rod, with or without the intervention of a beam. In stationary engines the shaft carries a fly-wheel, to distribute and equalize irregularities in the action of the power by its inertia; this func-

tion is performed in marine engines by the inertia of the paddle wheels or screw, and, in locomotive engines, by the inertia of the driving wheels and of the engine itself. The feed pump, and other pumps which are appendages of the engine, are worked by the mechanism; so also are the induction and eduction valves, through what is called the valve gearing or valve motion—a part of the machinery which is under the control of the engineman, and so contrived as to enable him to stop and reverse the motion of the engines at will, and whose forms are very various. Most marine and locomotive engines, and many stationary engines, have, in order to equalize the action of the power, a pair of cranks at right angles to each other, driven by a pair of pistons in a pair of cylinders, with their appendages.

STEAM ENGINEERING. Bureau of, a bureau of the United States Department of the Navy, established by act of Congress, 5 July 1862. Its duties as defined by the navy regulations comprise "all that relates to the designing, building, fitting out and repairing machinery used for the propulsion of naval vessels, the steam pumps, steam heaters, distilling apparatus, refrigerating apparatus, all steam connections of ships and the steam machinery necessary for actuating the apparatus by which turrets are turned." The engineer-in-chief of the navy is chief of the bureau. Rear Admiral R. S. Griffin was its chief in 1918.

STEAM GAUGE. See STEAM; STEAM-ENGINE.

STEAM HAMMER. See HAMMER.

STEAM HEATING. See HEATING AND VENTILATION.

STEAM JACKET, a space filled with steam surrounding the cylinder of a steam-engine; from it heat passes into the cylinder and prevents the condensation of steam which would otherwise take place during expansion.

STEAM VEHICLES or STEAM CARRIAGES, as the name implies, are carriages or conveyances in which steam is used as the motive power. The name is now usually applied to those vehicles which preceded the steam locomotive on rails and were designed for use on the ordinary highways. In 1824 David Gordon patented an arrangement for fitting to a steam-engine a set of jointed legs in imitation of the action of a horse's feet. In the same year Burstall and Hill made a steam-carriage in which the engine was like Evans', except that its cylinder was at the end of the beam and the connecting-rod in the middle. Earlier efforts to construct a steam-vehicle were made by Robinson and by Watt in 1759 and by Cugnot 10 years later, but it was not until the third decade of the 19th century that the steam-engine had been sufficiently developed to tempt inventors to try to adapt it to road service. In 1827 Gurney built a steam-carriage which worked for about two years in and around London, one of its trips covering 85 miles in 10 hours, including all stops. In 1828 he built a steam-carriage having a sectional boiler. Its cylinders were horizontal and the valve-gearing was driven by an eccentric on the rear axle. The link was moved by a cord running from the driver's seat. There was a separator to dry the steam, a forced draught and a feed-heater; and the valve cut off the steam at about one-half stroke. In 1829 Anderson and James built a road-engine which weighed three tons and carried 15 passengers on a rough graveled road at from 12 to 15 miles per hour. The same year Hancock built a road-engine with a boiler consisting of a collection of flat chambers with boiler-plate sides, the chambers being connected by tubes and stays. In 1831 he placed a steam-carriage on the road between London

and Stratford, where it ran regularly; while at the same time Dance had one running between Cheltenham and Gloucester, where it ran back and forth 3,500 miles, running nine miles, the distance between the two places, in 55 minutes and meeting with but one mishap, which was the result of malice. Ogle and Summer's steam-carriage ran from 32 to 35 miles an hour, carrying 250 pounds of steam. Hancock's *Infant* of 1831 ran from Brighton to London, carrying a party of 11, at from nine to 15 miles an hour. Hancock's *Autopsy* of 1833 went about the streets of London at all times without difficulty. By this time there were about 20 steam-carriages and traction-road engines running in England, where good roads had aided the inventors and builders; but hostile legislation checked the advance of this method of conveyance. Moreover the life of a steam-vehicle was very short, due to excessive vibration. No steam-carriage, steam-omnibus, street-locomotive or traction engine became a serious competitor to the horse carriage throughout the 19th century and in the closing years of the latter the automobile arrived, fitted with an internal combustion engine and pneumatic tires which eliminated all excessive vibration and the doom of the steam-vehicle was finally sealed.

STEAM VESSELS. The paddle wheel was in use for the propulsion of a vessel long before the application of steam to navigation. In the war galleys of the ancient Egyptians and Romans there were wheels operated by hand power through a windlass; and in one of the Punic wars the Romans transferred an army to Sicily upon vessels moved by wheels that were operated by oxen. Prince Rupert, after retiring from his military life, had a boat constructed on the Thames River, prior to 1680, that was propelled by paddle wheels, which were driven by horse power. It is thus clear that some form of paddle wheel for propulsion was made use of long before the steam-engine was in service. The Marquis of Worcester had experimented with the steam-engine from about 1655. He died in 1667 leaving a manuscript in which he says: "By this I can make a vessel of as great burthen as the river can bear to go against the stream. . . . And this engine is applicable to any vessel or boat whatsoever, without, therefore, being made on purpose. . . . It roweth, it draweth, it driveth, to pass London Bridge, against the stream at low water."

Early Steamboats.—The experiment narrated many years ago of Blasco de Garay in 1543 at Barcelona moving a vessel by steam power has long since been looked upon with doubt. This was 100 years before the steam-engine was put to any practical use even in its crude form. Denis Papin and Thomas Savery had proposed the application of steam to navigation about 1690, and the former is said to have applied it on a model at a later date. The name of Newcomen is also intimately associated with these earliest experiments and he is doubtless to be credited with having built the steam-engines used. In 1736 Jonathan Hulls of England obtained a patent upon what would be termed a stern wheel boat for towing purposes. The engine for this boat was made by Newcomen, and the vessel was

tested on the Avon but without enough success to attract needed capital, and no further efforts were made. Experiments were made in France from 1779 to 1783 by Genevois and Perrier, when the Marquis de Jouffroy built on the river Saône a steamboat of 150 feet long by 15 feet

Stevens' Screw Steamer (1804)

wide, which continued running with more or less success for 16 months, but defects developed in the machinery so serious as to cause the project to be abandoned for lack of money. Jouffroy proposed a company to build and operate steamboats, but failed to gain support. He has, however, been credited in history as the true inventor of the steamboat. Patrick Miller, a wealthy retired banker of Scotland, in 1788 had a double hull boat constructed 25 feet long and seven feet broad, and fitted with a steam-engine, under the supervision of William Symington. It succeeded so well that he built the next year a larger double hull boat, and a trial was made on the Forth and Clyde Canal in the summer of 1789, when seven miles an hour was made. The boat, the wheels and the engine were so ill proportioned to each other that the wheels were continually breaking, and the hull suffered so much from the strain imparted by the machinery as to be in danger of sinking. The trial was not considered to be a success, and the vessel was shortly after laid aside. It was now over 10 years before any further trials were made in Great Britain. It will be noted that John Fitch's experiments began in 1786, and Patrick Miller did not begin until some two years later. Symington had not lost faith in the project, and succeeded finally in interesting Lord Dundas, one of the proprietors of the Forth and Clyde Canal, in steam propulsion for canals, and with his support in 1801 built the *Charlotte Dundas*, a stern wheel boat to tow the canal boats on the canal, instead of towing with horses. The vessel was 56 feet long, 18 feet beam and 8 feet in depth and was fitted with an engine of 22 inches cylinder by four feet stroke. The trial was made in March 1802 with two boats in tow, and three and one-half miles per hour was made for a distance of nearly 20 miles. A great clamor arose as to the probable destruction of the banks of the canal from the violent agitation of the water produced by the paddle wheel, and the project was abandoned. A further effort by Symington, under the patronage of the Duke of Bridgewater, came to an end with the death of the duke and Symington, reduced to poverty, withdrew from further endeavor. It

was now 10 years before another steam vessel was built in Great Britain, and in the meantime Livingston and Fulton had constructed four steamboats for the Hudson River, and the *Raritan* for the New Jersey line, and the *New Orleans* for the Western rivers; while John Stevens had built the *Phanix* and sent her to sea from New York to Philadelphia, Pa. This vessel was built in 1812 at Glasgow by John Wood for Henry Bell, and was the first successful steam vessel in Great Britain. The hull was 42 feet long by 11 feet beam and five feet six inches deep, and named *Comet*. By means of spur wheel gearing the power was transmitted to two pairs of paddles. As this arrangement proved to be unsatisfactory the vessel was fitted with a single pair of wheels, and the hull was lengthened to 60 feet, and the engine power increased. The speed of this vessel was originally five miles per hour. Robertson, the engineer of the *Comet*, succeeded in so improving her engines as to raise the speed to six miles per hour. His success led him into steamboat building on his own account, and in 1813 he started the *Clyde*, and in 1814, the *Tay*, *Caledonia* and *Humber*, all of which proved commercially profitable. The first iron hull steam vessel built in Great Britain was in 1822 named the *Aaron Manby*, built at the Horsley Iron Works near Birmingham. The vessel was 166 feet long and 16 feet beam, and fitted with a 30 horse-power engine operating "Oldham's Revolving Oars that enter and leave the water edgewise."

First American Steam Vessels.—The period when the first experiment with a steam vessel in the United States was made, so far as the mechanical side was concerned, was anything but inviting to those interested. There was not in the United States at the time one steam-engine in use, and it is doubtful if the first principles of its working were understood. The American people were comparatively poor at this time, having but a few years prior to this date returned to the peaceful pursuits of life after the long and costly War of the Revolution. After a few years the "steam mania" broke out, and the application of steam to navigation was under trial. To John Fitch of Connecticut must be given the credit for the first steamboat in the United States, imperfect as it was. He made his first trial on 22 Aug. 1787, but was not able to attain more than three miles an hour. This boat was propelled "by 12 oars or paddles five and a half feet, which work perpendicularly and are represented by the stroke of the paddle of a canoe." Then in 1789 another boat was built that was fitted with more power, that developed on trial a rate of speed of eight miles an hour. These experiments were carried on by a company who furnished the capital for the enterprise, and not meeting with the success anticipated after three years' labor, refused to advance any more funds for the further prosecution of the enterprise, thus leaving Fitch to carry on his trials on his own account. This he did for a short time only, as he was unable to procure the means for the necessary changes in the vessel, and it was this financial condition that finally forced him to abandon the whole business, and he went to France and England with his drawings, but met with no better fortune. Upon

his return in 1796 he made an experiment on the Collect Pond in New York in a common yawl boat, with both side wheels, and again with a propeller at the stern of the boat. Nothing seems to have come from these later experiments. Fitch has been described as having been brought up from manhood as a watch-maker, and being fond of mechanics through the prosecution of his trade, he was continually experimenting along different lines, and at last drifted into the application of steam to navigation. He no doubt had a small knowledge of the steam-engine, but his peculiar disposition, ever urged on by his impulses, subjected him to many disappointments. There is no doubt he accomplished more in propelling his boats than some others have done at a later date. James Rumsay, a native of Maryland, and a strong competitor in the experimental stage of steam navigation with John Fitch, constructed in 1784 a boat that was propelled by cranks and a series of "setting poles." This project was soon abandoned. In 1787 he constructed a boat about 50 feet long, that was propelled by admitting water through a trunk on the keelson of the vessel, and by means of a steam pump discharging it at the stern. This boat was never put to any practical use. Leaving the United States to his opponent, Rumsay sailed for London, where he built another vessel, but he died in 1793, following a successful exhibit of his craft. Another name connected with the earliest experiments with steamboats in America is that of Samuel Morey, who in 1790 ran a small boat with a paddle wheel at the bow on the Connecticut River, and in 1797 operated a side-wheel steamboat on the Delaware River. To Oliver Evans, an engine builder of Pennsylvania, must be given some credit for his trials in steam navigation. In 1802 he was called on to construct an engine of nine inches cylinder by 36 inches stroke, for a boat of 80 feet long and 18 feet beam, built in Kentucky for Capt. James McKeever, United States navy, and Louis Valcourt, and floated to New Orleans, La. Before the vessel was completed the river had fallen so much as to leave the vessel high and dry on shore. The engine and boiler were taken out and placed in a saw-mill, where they were in use until the mill was destroyed by fire. In 1804 he constructed for the city of Philadelphia a machine for dredging the slips of the city. The machinery was fitted in place on a large scow 30 feet long by 12 feet beam, and was driven by a stern wheel that was operated by a small steam-engine. It was driven down the Schuylkill River to the Delaware River, and up the latter river, in all some 14 or 15 miles.

Robert Fulton.—After the withdrawal of Fitch from the activities of steam navigation, and the death of Rumsay, there does not seem to have been that mania for the application of steam to navigation. It languished for a time, but not long: for Robert R. Livingston of New York, who had been interested in Morey's experiments, was granted by the New York legislature the exclusive privilege of navigating the waters of the Hudson with a vessel propelled by steam. Livingston was a man of wealth, and had a taste for mechanics. He was associated with John Stevens and Nicholas J. Roosevelt in experiments with a steamboat

that year, but the results were unsatisfactory, the best speed attained being three miles per hour, while the State requirements were four miles. Other trials were made the next year with another vessel, but with no better success. The grant by the State had now expired. Robert R. Livingston had been appointed Minister to France, and while there had met Robert Fulton, who had been engaged in experiments with the application of steam to navigation, among other things, and in 1803 made a trial with a boat propelled by paddle wheels, which showed

Fulton's *Clermont* (1807)

with improvement in the engine they might look for better results. The French paid no attention to these achievements, and Fulton accompanied Livingston back to America. Livingston had the legislative privileges restored to him and Fulton, for two years, by the legislature. As those were not complied with, it was extended in 1807 for two years. John Stevens, then of New York, but later of Hoboken, N. J., was also a man of large means, with a mechanical turn of mind. His trials with the screw propeller began in 1802 and lasted until some time in 1806. In 1804 he had in operation on the Hudson a small vessel with a tubular boiler propelled by twin four-bladed screws, which attained a speed of about nine miles per hour. This was the first practical application of the propeller to a vessel. But the men who at that time were working with steamboats had their minds set upon paddle-wheels, and the screw propeller was ignored. Robert Fulton before leaving Europe in 1806 had parts of a steam-engine built to his order by Boulton and Watt of Birmingham, England, that were shipped to New York. He had the hull of a vessel constructed at New York in 1806-07, and the engine from Boulton and Watt was fitted on board. This vessel was named *Clermont*. It was 140 × 13 × 7 feet deep, and the engine having a bell crank motion, had a cylinder of 24 inches diameter and four feet stroke. Her trial trip from New York to Albany was commenced on 17 Aug. 1807. The vessel was enlarged during the following winter and rechristened the *North River*. As there was no part of the original *Clermont* that was an invention of Robert Fulton, though he obtained patents at a subsequent date on improvements, his theoretical knowledge of steam navigation and its adaptation to practical purposes was the cause of his success. He knew very nearly all that had been done in the way of experiments, and his ability lay in selecting those features that were of value and bringing them together so

they were first seen in the *Clermont*. He must certainly have had mechanical ability of no mean order for that day to have accomplished so much at one stroke. The first complete American-built steamboat, both hull and machinery, was the *Phenix*, constructed in 1808 by John Stevens; and as Fulton held the exclusive privilege of New York waters for steam vessels, Stevens sent the vessel around to the Delaware River, leaving New York 8 June 1809, to form part of a line between New York and Philadelphia. About the same time the *Raritan* was built to run from New York to New Brunswick, N. J., to form the New York end of the New York and Philadelphia line. This vessel was run in the interest of the New York monopoly.

Early Ferry-boats.—Fulton and his associates, or the North River Steamboat Company, met much opposition in the proposition of their enterprise, and it became so bold after a time in placing obstacles in the way, during the running of their vessels, that they were compelled to resort to the legislature of the State for a law to protect them in their lawful rights. There was one company which built two boats that were originally fitted with experimental engines, that were removed almost as soon as erected on board, and steam-engines and boilers substituted, in defiance of the monopoly of the Fulton company. After three years in the courts the vessels were delivered into the possession of the Fulton company, who broke them up. This exclusive privilege was the cause of a petition being laid before the New York legislature in 1814 by Aaron Ogden of New Jersey, who desired to run a steamboat on his ferry to Elizabethtown, N. J., but was prevented by Livingston and Fulton. The matter was at length compromised so that Ogden ran his boat. He had a partner in his ferry property named Thomas Gibbons of Savannah, Ga., who opened an opposition line to Ogden, and it was on this route and line Cornelius Vanderbilt began his steamboat career. This opposition, commenced in 1818, was the cause of the lawsuit that was carried to the United States Supreme Court, where in 1824 a decree was entered against Ogden, thus breaking down the steamboat monopoly. The steam ferry-boat was first brought into use by Robert Fulton, on the Fulton ferry running from New York to Brooklyn in May 1814.

Hudson River Boats.—After the waters of the United States were thrown open to the free navigation of steamboats in 1824, the number of steam vessels increased on the Hudson River, as that was the most expeditious mode of travel from New York to Albany, as well as the best patronized channel of travel from the seaboard to the Western States, that were just then being opened to the settler. The new vessels were great improvements over the vessels of the North River Company, that now in many instances became tow-boats. For nearly 10 years later several lines were formed that were well backed financially for that period, until in 1832, when they were all consolidated. In 1835 the People's Line was opened with the *Westchester* and the *Emerald*. The most noted of the boats of this period were the *Swallow* and the *Rochester*, that were rivals on the New York and Albany route, and for several years

were very often engaged in racing. This was the opening stage of that fierce rivalry between the lines on the river that was so well known for many years, when at times, so intense has been the competition, passengers have been transported the entire length of the navigable river free of cost of carriage. This lasted until 1852, when the steamboat law went into effect, which brought the operation of our steamboats under the United States law. And it was well it did even at that late date. The completion of the Hudson River Railroad in the latter part of 1851 had a great effect in diminishing the number of steamboats on the river. Since then the business on the river has been in the hands of companies that have been strong financially, and who have catered to the public travel with the better class of vessels suited to the service. The present Hudson River Day Line was started in 1863 with the *City of Albany*, and was incorporated in 1879. The People's Line of night boats, or New Jersey Steamboat Company, had built in 1896 the *Adirondack*, that was a marked advance upon the form of the previous vessels of the line. Their first steel hull vessel, the *C. W. Morse*, appeared in 1904. The second *Hendrick Hudson* was launched in 1907, and leads the Day Line fleet, which includes also the *Robert Fulton* and the *Washington Irving*. There have been at different periods several fine boats on the river possessed of high speed that may be mentioned, such as the *Daniel Drew*, *Mary Powell*, the fastest vessel known until the torpedo-boat destroyer was devised, having a speed record of 27 miles per hour; *Thomas Powell*; the *Alida*, and the first *Hendrick Hudson*.

Long Island Sound.—Communication by water on Long Island Sound dates back to 1813-14 when the *Fulton* was constructed for service from New York to New Haven by Captain Bunker, whose boats *Hobe* and *Perseverance* on the Hudson had been seized by Fulton and Livingston under their monopoly, and broken up. On account of the War of 1812 and the activity of the British naval vessels off our coast at the time, it was deemed prudent to postpone the opening of the new line. It was not until 21 March 1815 that the vessel was placed on the route. The *Firefly* was the first steamer to round Point Judith and sail into Newport. This was in May 1817. In 1818 the *Connecticut* was brought out in the same interest, and run from New York to New Haven, while the *Fulton* was run from New Haven to Norwich, Conn., as it was considered unwise to run a boat on such a long route as from New York to Norwich, Conn., at that time. These vessels thus ran until prevented by the passage of the retaliatory law by Connecticut in 1822, when they ran to Providence, R. I. The *United States* was purchased in 1822 by New Haven parties and ran to Byram Cave, N. Y., and this service continued until the exclusive privilege of Fulton and others was declared unconstitutional, when the vessel was run direct from New York to New Haven. This was the beginning of the New Haven Steamboat Company. Other vessels followed of improved construction, and larger and better accommodations. They had their periods of opposition and low fares as on other important routes. One of the fastest vessels that has thus far been on the

line has been the *Richard Peck*. In 1899 a duplicate of this vessel, the *Chester W. Chapin*, was added to the line. Providence, R. I., was first served with a steamboat line in 1822. In the following six years three new steamboats were built for the line to New York, and during

The Side-lever Engine (1849).

this period opposition began on the route. This had then become the most popular route from New York to the Eastern States. In 1835 Cornelius Vanderbilt placed the *Lexington*, then a new boat, on the route, and being one that developed in a short time higher speed than those on the old line, drew a greater portion of the passenger travel. The Boston and New York Transportation Company had the *Boston*, the *Providence* and the *Massachusetts* in 1836. The *Lexington* was again on the route in 1836, and having made it lively for the old company, they had the *Narragansett* built, to be on even terms with the opposition, as they thought; but they were mistaken. The *Lexington* was purchased by the Transportation Company in 1838, as another opposition line with the *J. W. Richmond* had presented itself for public favor. The *Lexington* took fire while on a trip from New York to Stonington on 13 Jan. 1840 when off Eaton's Neck, Long Island. There were at least 150 persons on board, and all were lost except four. After 1845 the passenger service to Providence fell off to a great extent, and it was many years before it was resumed with a first-class passenger line. Stonington had become the popular route. The New Jersey Steam Navigation Company controlled the business of this route from 1840 to 1867, when they withdrew their boats from the service. A first-class passenger line was not resumed to Providence until 1877, when the *Rhode Island* and the *Massachusetts* were placed on the route by the Stonington Steamship Company, and then began the war of rates that lasted so long on Long Island Sound. These boats were followed by the *Connecticut*, and later by the *Plymouth* and others. The Joy line commenced running to Providence in 1899. After the Stonington line was closed up in 1867 there were no steamboats running to Stonington until January 1868, when the Stonington Railroad

Company and others organized the Stonington Steamship Company, and ran the *Narragansett* and the *Stonington*. These vessels were succeeded by the *Rhode Island* (No. 3) and later by the two propellers *Maine* and the *New Hampshire*. The Fall River Line was opened in 1847 with the *Bay State*, much the largest and fastest steamer of her time, and the next year the *Empire State* was added, and a few years later the *Metropolis*. The company was reorganized in 1863 and a new fleet of boats built for the line that did service until the consolidation with the *Narragansett Steamship Company* in 1874. The two famous steamers *Bristol* and *Providence*, of the Merchants' Shipping Company, merit distinguished remembrance. The first iron hull vessel, built with 96 water-tight compartments, was the *Pilgrim*, added to the Fall River Line in 1883, and subsequently the floating palaces, *Puritan*, *Plymouth* and *Priscilla* were placed in commission. The *Commonwealth*, the largest and fastest of the Fall River fleet, represents the very highest type of American river steamer of the sturdier class of side-wheelers. To New London and Norwich, Conn., there were several lines run up to 1860, when the *Norwich* and New York Transportation Company was organized, and the *City of Boston* and *City of New York* were built. A few years later three smaller passenger and freight boats were built. In 1881 their first iron hull steamboat, *City of Worcester*, was placed in service, and in 1894 the steel hull twin-screw propeller *City of Lowell* was added to the line. This vessel has proved to be one of high speed.

Lake Steamers.—Steam navigation on the Great Lakes dates from the year 1818 when the *Walk-in-the-Water* was built to run on Lake Erie. The most radical departure in steamboat design and construction on the Lakes was in the building of the *Great Western* in 1838, by the adding of the upper cabin with staterooms, and converting the lower cabins into steerage quarters and freight compartments. There were several fine and large side-wheel passenger boats built after 1845, after the general style of the Long Island Sound boats. By 1849 there were 29 side-wheelers and 10 propellers running out of Buffalo; and by 1862 the number had increased to 147 side-wheelers and 203 propellers. The extension of the railroads along the shore of Lake Erie soon made their business unprofitable. Since 1880 there have been several large iron or steel hull passenger boats built to run from Buffalo and Cleveland to Detroit, and fitted with large engine power, that have proved themselves to be vessels of very high speed. Lake Ontario had its first steam vessel in the *Lake Ontario* built in 1816. There were several lines of beam-engine boats on the lake up to 1860, when the railroads, having absorbed the greater part of the business, several of the vessels were brought to the coast by running the rapids of the Saint Lawrence River. The finest passenger steamer on the Great Lakes is the *City of Cleveland*, running between Detroit and Cleveland. The largest cargo vessel in those waters is the *William M. Mills*, with a capacity of 514,500 bushels of wheat, or 12,380 tons of iron ore. Prominent among the Canadian-built lake steamers are the immense freighters *Collingwood* and *Midland Prince*.

Coast of Maine Steamboats.—The coast of Maine was first visited by a steam vessel in 1823. There were many vessels running from Boston, Mass., to Portland, Me., and the coast towns up to 1845, when the Sanford line began operations. The Portland Steam Packet Company began their operations in 1843. The iron hull propeller *Bangor*, running from Boston to Bangor, Me., began its service in 1845. The International Steamship Company, running from Boston to Saint John, New Brunswick, began operations in 1859. All the lines running from Boston to the coast of Maine were consolidated in November 1901.

Western River Steamboats.—The first steamboat constructed for the Western rivers was the *New Orleans*, built at Pittsburgh, Pa., in 1811 under the supervision of Nicholas J. Roosevelt for Livingston and Fulton. Several vessels were constructed for these waters dur-

River Steamer (1895).

ing the next decade, but of a different form of hull and type of engine, several of them being more like those of a later date. The conditions under which the steamboats on the Western rivers are operated are so different from those on other rivers of the United States that they are required in design to conform more closely to the surrounding conditions. The shallowness of the channel makes it necessary for the hulls of these vessels to be of great length and width in proportion to the depth of hull. The engines are all poppet valves, worked by levers, with the cylinders set horizontally on wooden frames, generally. The boilers are usually plain cylinder with two flues each. They are worked non-condensing under a pressure of 100 to 125 pounds to the square inch. They are usually fitted with side wheels, but the stern-wheel boat has been favored for some service. There were a few compound engines in boats on the rivers several years ago, which type of engine has gained in favor again on the Western rivers in more recent times. Before the railroads in the Western States became so numerous, the passenger and freight business in that section of the country was largely carried on by the steamboats, and at that time there were many fine and fast steamboats on the Mississippi and the Ohio rivers, and a few of large dimensions. Among the earlier steamers on the Mississippi were the *Moselle* and *Oronoko*, memorable for their boiler explosions; and the *Pioneer* and *Ontario*, which raced often on the Ohio. There was in 1852 the *Eclipse* of 363 feet long with two engines of 36 inches by 11 feet stroke each. The *J. M. White* of 1844 of 250 feet long, with two engines of 30 inches by 10 feet stroke each. Then at a later date the *Grand Republic* of 1876 of 350 feet long with two engines of compound type. The *J. M. White* of 1878 was 321 feet long with two engines 43 inches by 11

feet stroke each, and water wheels 45 feet diameter and 18 feet 6 inches face. The famous race of the *Natchez* and *Robert E. Lee* on the Mississippi River began on the afternoon of 30 June 1870 from New Orleans, and ended at Saint Louis on the morning of 4 July. The latter made the 1,218 miles in 3 days 18 hours and 30 minutes. The *Natchez* had run into a fog and grounded about 300 miles below Saint Louis that delayed her about six hours.

Ocean Steamships.—There have been a few attempts made to dispute the claim of the *Savannah* as the pioneer steamship of the Atlantic Ocean, but when these attempts have been closely examined it still leaves the American vessel at the head of the list. She was constructed at New York in 1818 by Francis Fickett as a sailing packet originally, but an auxiliary engine and boiler with paddle-wheels were fitted before she was placed in service. She was owned by parties at Savannah, Ga. On 24 May 1819 she left Savannah for Liverpool, England, which port was reached in 27 days, 80 hours of which time she was operated by steam power. On 29 September she started on her return to the United States, stopping at Saint Petersburg, Stockholm and other Baltic ports, and arrived at Savannah 30 November. Subsequently her machinery was removed and the hull converted to a sailing vessel, and run between New York and Savannah, Ga., until driven ashore on Great South Beach on Long Island, 5 Nov. 1821, during a gale, where she became a total loss. The *Rising Star*, built for the government of Chile, made the next westward crossing of the Atlantic in 1822, arriving in Valparaiso in April. She was a full-rigged ship with an auxiliary steam-engine. There was a long interval of time before another American steamship crossed the Atlantic Ocean, but during that period much knowledge had been gained of steam navigation that was of use in constructing ocean steamers. The Ocean Steamship Company in 1847 had the *Washington* and the *Herman* built for a line from New York to Bremen, they having obtained a contract to carry the United States mail for 10 years. In 1849 the New York and Havre Steam Navigation Company obtained a contract to carry the United States mail to Havre, and during the same year had the *Franklin* and the *Humboldt* constructed for the line. The latter vessel having been lost in 1853, and the former in 1854, the company ran the line with chartered vessels until the *Arago* and the *Fulton* were built and placed on the line in 1855. This line was well managed and received more American patronage than any other running to the same ports. These vessels ran until the opening of the Civil War in 1861. The next line of American ocean steamships was the Collins line, organized about 1847 as the New York and Liverpool United States Mail Steamship Company. The *Atlantic* and the *Pacific* were built in 1849, and the next year the *Baltic* and the *Arctic* and *Antarctic* were constructed for them at New York. The general dimensions of these vessels were each 277 feet long, 45 feet beam and 31 feet depth of hold. Their motive power was a pair of "side lever" engines, the first two vessels built having cylinders 95 inches by 9 feet stroke, while the others were larger. These engines were of

1,000 horse power and the vessels were of 2,860 tons. The line started under a contract to carry the mail for \$385,000 per annum, which was subsequently increased to \$858,000: yet with this large mail pay or subsidy, just as it is viewed, and a large share of the passenger travel and freight, it failed to be a paying line. The rivalry existing with the Cunard line at this time was very great and the expenses of operation in making record time voyages made a heavy drain upon the finances of the company. There were also commercial and political interests that were antagonistic to the company, so that by 1857 Congress had cut down the appropriation for mail pay to less than the original amount; and as the line could not be operated successfully under these conditions the last vessel was withdrawn from the route in January 1858. Congress virtually "froze out" the company. The *Adriatic*, a vessel of 4,150 tons, was added to the fleet in 1857, and made but one voyage in the line. The remaining vessels afterward passed into other hands. The *Arctic* was lost by collision off Cape Race on 27 Sept. 1854; and the *Pacific* sailed from Liverpool on 23 Sept. 1856 and was never heard from afterward. The *Atlantic* was broken up in September 1871; and the *Baltic* was broken up about 1880, having for some time been run as a sailing vessel, her machinery having been removed. Cornelius Vanderbilt in 1855 began the operation of a line of steamships to Southampton and Havre with the *North Star* and the *Ariel*, and during the next year ran to Bremen. At this time he had built the *Vanderbilt*, his largest ocean steamship, that ran with some one of his large fleet of ocean steamships, to either Bremen or Havre until the opening of the Civil War. There were a few attempts made after 1865 to build up an American transatlantic line from New York, but they all ended in failures. It was also tried from Boston by the American Steamship Company, who had in 1866-67 the *Erie* and the *Ontario* built. The latter vessel made one voyage and returned, when laid up; while the former never made a voyage in the line.

The names of the great steamships which have ploughed the waters of the seven seas are legion and but a few may be mentioned here. For the five years following the outbreak of the Great War no notable steamships were placed in commission. The *Leviathan* of 1914 (formerly the German *Vaderland*) is still (1919) the world's largest merchant steamship; 950 feet in length, 100 feet beam and a displacement of 58,000 tons. Its four turbines of 90,000 horse power drive four propellers, attaining a speed of 25.8 knots. The *Imperator*, also a German vessel seized by the United States in the war, is the second largest of the world's vessels. It was placed in commission in 1913. It is 909 feet long, 98 feet beam and of 52,000 tons displacement. Its turbines drive four propellers with 60,000 horse power, developing a speed of 22.5 knots. The *Aquitania*, a Clyde-built steamer of 1914, has a length of 901 feet; beam of 97 feet; displacement of 53,000 tons; engines of 60,000 horse power and a speed of 23.5 knots. The *Olympic*, of 1911, has a length of 883 feet; beam of 92½ feet; displacement of 52,000 tons; engines of 60,000 horse power; and a speed of 22.5 knots. The *Mauretania* (1906)

is 790 feet long; 87½ feet beam; 41,550 tons displacement; with engines of 74,000 horse power, developing a speed of 26.06 knots. These are the five largest vessels now in ocean service.

The American Liners.—In 1871 the American Line, controlled by the Pennsylvania Railroad Company, was organized to run a line of steamships from Philadelphia, Pa., to Liverpool. It will be noted that this was at the beginning of the period when iron shipbuilding in the United States began to increase, and the compound marine engine was coming into favor. The company had built in 1873-74 the *Pennsylvania*, *Ohio*, *Indiana* and *Illinois*. These proved to be good, staunch and serviceable vessels for the line, though only of average speed under good conditions. They subsequently passed into the hands of the International Navigation Company, which absorbed the Inman line in 1886. The present American line is the result of an act of Congress of 1892, providing with other conditions that certain foreign-built steamships should receive American register on condition that steamships of corresponding tonnage were built in the United States. This led to the *City of Paris* and the *City of New York* receiving American register in 1893, and their names being then abbreviated *Paris* and *New York*. Contracts were then made with the William Cramp Ship and Engine Building Company for the *Saint Paul* and the *Saint Louis*, they having the first quadruple expansion engines built in the United States for the Atlantic service. These vessels ran to Southampton and Cherbourg. They are elegantly fitted and furnished in their passenger accommodations, are well patronized by the American traveling public and have shown on more than one occasion that they are possessed of more than average high speed. In January 1903, the American and Red Star lines were consolidated with four British lines as the International Mercantile Marine Company.

Coastwise Steamships.—The *Robert Fulton*, built in 1819, was the pioneer in the coastwise trade with steam vessels and ran between New York and the island of Cuba from 1820 to 1825, when it was sold to the Brazilian government. There were no steam vessels running coastwise from the latter date till 1832, when a small steamboat named the *David Brown* was refitted and run from New York to Charleston, S. C. In the next six years there were five larger vessels built for the same route, but of the same general type of vessel. After the loss of one of these vessels in 1837, public confidence in their safety became so shaken that they no longer found profitable employment on the route, and in a short time were withdrawn. The first steamships to be employed along our coast were those built in 1846-47 to run between New York and Charleston, S. C., the *Southerner* and the *Northerner*. These vessels were the pioneers of the many steam vessels that were built in a few years to run on lines between the Atlantic ports. The largest development of our early ocean steam marine began with the discovery of gold in California. During the Civil War these coastwise lines of side wheel steamers were discontinued. Then they were opened again and gradually fell into financially strong hands.

Most of them after 1870 began the construction of iron hull vessels with compound propeller engines, and by 1880 had laid aside the wooden hull vessels with the expensive beam-engine or the simple condensing propeller engine, so that at the present time we find a fine fleet of large vessels running from all our principal ports on the coast that are operated at a much less cost for same size of vessel than those in the same service 30 years or more ago.

Whalebacks.—These vessels have a main deck rounded over, and resemble the back of a whale. They are for use in rough water, the waves passing completely over them without resistance or injury. The first one was built for a Baltimore company about 1860. Such vessels are now used as grain carriers on the Great Lakes; and more recently as passenger vessels. As oil-carriers this type has been very successful upon the deep sea. Their average speed is nearly 20 miles per hour.

Double Screw Ferry-boats.—This type of vessel, having a screw at each end of the vessel, is, for ferry service, of comparatively recent date, although double-screw steam vessels were built in this country many years ago. These vessels must not be confused with a twin-screw vessel having two screws at the stern of a vessel. The pioneer of the later development was the *Bergen*, built in 1888 for the Hoboken ferry, having a triple expansion engine. Since then this type of ferry-boat has been growing in favor until at this time it has practically driven the old-fashioned side-wheeler out of use; except on the shorter ferries.

Screw Propellers.—After John Steven's experiments with the screw propeller in 1802 to 1806, there was nothing done in this country to practically demonstrate the value of the screw until the *Robert F. Stockton*, having an Ericsson propeller, was brought to this country in 1839. Then the propeller began to come into use, both on the Atlantic Coast as well as on Lake Erie and Lake Ontario, and it is altogether probable that its largest development in the first decade was on the northern lakes.

Summary.—The progress in the development of the modern steam vessel may be summarized by divisions into decades marked by salient advances.

Between 1845 and 1855 iron was substituted for wood in the hulls of steam vessels and the boiler pressure was advanced from 10 pounds to 20 pounds per square inch; the coal consumption being reduced from 4.5 pounds to 3.5 pounds per horse power per hour.

Between 1855 and 1865 the screw-propeller took precedence of the paddle-wheel as a means of propulsion; the boiler pressure was increased to 35 pounds; and the coal consumption dropped to three pounds per horse power per hour.

Between 1865 and 1875 the compound engine was introduced; the boiler pressure went up to 60 pounds; and the coal went down to 2.5 pounds per horse power per hour.

Between 1875 and 1885 steel superseded iron in hull construction, and the triple-expansion engine came into use. The boiler pressure was advanced to 125 pounds, and the coal consumption fell to two pounds per horse power per hour.

Between 1885 and 1895 twin screw propulsion with quadruple expansion engines and the principle of the forced draught were brought into use. The boiler pressure rose to 200 pounds, and the coal consumption dropped to 1.5 pounds per horse power per hour.

The decade 1895 to 1905 was one of transition. A few turbines appeared and the steam pressure in compound engines reached a maximum of 225 pounds.

Between 1905 and 1915 turbine engines came generally into use, and the boiler pressures came down to 160 to 175 pounds, at which figures the turbines were most effective. The coal consumption also decreased to 1.2 pounds per horse power per hour. See also SHIP-BUILDING; WARSHIPS.

STEARATES. See STEARIC ACID.

STEARIC ACID. N—Octadecylic Acid, $C_{18}H_{36}COOH$, occurs in large quantities as a glycerol ester in animal and vegetable fats. Palmitic acid, $C_{16}H_{32}COOH$, and oleic acid, $C_{18}H_{34}COOH$, are usually associated with stearic acid in these sources. Animal fat contains the glycerol esters of all three acids in varying quantities, depending upon the nature of the fat. Shea-butter, a vegetable fat obtained in West Africa, contains the glycerol esters of stearic and oleic acids only. When these fats are saponified and then treated with a mineral acid, a mixture of these acids is produced. In the preparation of these acids from fat, saponification may be brought about by the use of lime, superheated steam or sulphuric acid. The mixed acids are fractionated by first pressing between warm plates in order to remove liquid oleic acid. The residue is then dissolved in alcohol and poured into an alcoholic solution of magnesium acetate; magnesium stearate precipitates first, yielding free stearic acid when treated with a hot solution of hydrochloric acid. The product may be purified by crystallization from alcohol.

A number of synthetic processes have also been developed for the preparation of stearic acid. It may be obtained: (1) By heating oleic acid with hydrogen iodide and red phosphorus at 200°–210° C.; (2) by the direct addition of hydrogen to oleic acid, or other unsaturated acids, in the presence of nickel or other reduced metallic substances; the metals acting as catalysts. According to United States patent 1,209,512, stearic acid, suitable for the manufacture of candles or high-grade fatty soaps, can be produced by hydrogenating finely divided nickel, until the iodine number is reduced to zero and the melting point is raised to 62° C. The product is saponified and the acids extracted are purified. Stearic acid is a white crystalline solid with no taste or smell. It melts at 69.32° C. and boils at ordinary pressures with partial decomposition at 360° C. The acid is insoluble in water, but will readily dissolve in boiling alcohol and ether. The

potassium or sodium salts of stearic acid are the chief constituents of soft or hard soap. Commercial stearic acid, known as "stearin," contains a large quantity of palmitic acid. In order to destroy its crystalline structure stearin is usually mixed with wax or paraffin; it is extensively used for the manufacture of candles, stove polish, shoe polish and varnish. Pure stearic acid is used for the preparation of glycerin suppositories.

STEARNS, Frederick Pike, American hydraulic engineer: b. Calais, Me., 11 Nov. 1851. He was connected with the city surveyor's office, Boston, Mass., in 1869-72; with the construction and maintenance of the additional water supply of Boston in 1872-80; with the main drainage works of that city in 1880-86. He was chief engineer of the Massachusetts State Board of Health in 1886-95; a member of the board of sanitary engineers to devise a sewage system for the District of Columbia in 1889-90; and chief engineer of the Massachusetts Metropolitan Waterworks in 1895-1907. He served as consulting engineer to the Charles River Basin Committee in 1903-10 and to the New York Board of Water Supply from 1905. He was a consulting engineer of the Panama Canal in 1905-06. He served on the boards making reports on the Los Angeles waterworks in 1908, the Baltimore water supply in 1908-09, and that of Winnipeg in 1913. He has been consulting engineer for the new water supply of Providence, R. I., since 1914. He was president of the American Society of Civil Engineers in 1906.

STEATITE, the mineralogical name for soapstone. See **TALC**.

STEBBINS, George Coles, American evangelistic singer: b. East Carlton, N. Y., 26 Feb. 1846. He studied music in Rochester, Chicago and Boston. He was director of music at the First Baptist Church, Chicago, in 1870-74, and at the Clarendon Street Baptist Church, Boston, in 1874-76. In 1876-99 he was engaged in evangelistic work as a singer with D. L. Moody and I. D. Sankey, touring the United States and Great Britain. He later made tours in Egypt, Palestine and Europe. From 1880 he was conductor of music at the Northfield, Mass., Conference. He collaborated with Sankey and McGranahan in editing 'Gospel Hymns' (Nos. 3-6), and compiled 'The Northfield Hymnal' (1904).

STEDMAN, Charles, English military historian: b. Philadelphia, Pa., 1753; d. London, England, 26 June 1812. He was educated at the William and Mary College. In the Revolutionary War he enlisted in the British army and served at Lexington, Bunker Hill and under Cornwallis in the south. At the end of the war he was retired on the half-pay of a colonel and returned to England. He served on a committee to examine and settle the claims of the American loyalists, and in 1797 was appointed deputy controller and accountant-general of the stamp office. His 'History of the Origin, Progress and Termination of the American War' (2 vols., London 1794) is the standard British work on the American Revolution and contains military maps of high value.

VOL. 25 — 36

Its accuracy in minor details was questioned by Sir Henry Clinton in 'Some Observations upon Mr. Stedman's History' (1794).

STEDMAN, Edmund Clarence, American poet and critic: b. Hartford, Conn., 8 Oct. 1833; d. New York City, 18 Jan. 1908. He studied at Yale, and in 1856 began contributing to various New York journals. He was Washington correspondent of the *World* in 1861-63; he held a post in the office of Attorney-General Bates; but in 1869 entered business in New York, where until 1900 he was a member of the stock exchange. After the appearance of his first collection, 'Poems, Lyric and Idyllic,' in 1860, he published several books of verse, such as 'The Blameless Prince, and Other Poems' (1869); 'Hawthorne, and Other Poems' (1887); 'Lyrics and Idyls, with Other Poems' (1879); and 'Poems Now First Collected' (1894). 'Pan in Wall Street' is one of his best poems. His 'Victorian Poets' (1875) passed through many editions. It is a judicial, careful and sufficiently learned work, and much better than his 'Poets of America' (1885). He also edited a 'Victorian Anthology' (1895) and 'An American Anthology' (1900), the latter of which was criticized for too great catholicity, while both displayed wide knowledge. The 'Library of American Literature' (1888-89) was prepared by him with E. M. Hutchinson. His Turnbull lectures at the Johns Hopkins University and repeated at Columbia and Pennsylvania universities appeared as 'The Nature and Elements of Poetry' (1892). His other works include 'Alice of Monmouth,' 'Genius and other Essays,' 'The Works of Edgar Allan Poe' (with G. E. Woodberry). Consult Stedman and Gould, 'Life and Letters of Edmund Clarence Stedman' (New York 1910); Winter, W., 'Old Friends' (New York 1909).

STEDMAN, Elizabeth Clementine (Mrs. William Burnet Kinney), American writer, mother of E. C. Stedman (q.v.): b. New York, 18 Dec. 1810; d. Summit, N. J., 19 Nov. 1889. She was a sister of D. L. Dodge, the philanthropist, was married to E. B. Stedman in 1830 and was widowed in 1836. She was married to W. B. Kinney, a newspaper publisher, in 1841, and in 1851, when her husband was appointed on the Sardinian mission, she accompanied him to Turin. She was already known as a contributor to the *Knickerbocker*, *Blackwood's* and other magazines, and in the 14 years she remained abroad with her husband she wrote extensively on matters of art, travel and scenery. In Italy she was associated with an interesting literary circle, among whom were the Brownings. She wrote 'Felicità' (1855); 'Poems' (1867); 'Bianca Capello, a Tragedy' (1873), etc.

STEDMAN, Fort. See **FORT STEDMAN**.

STEEDMAN, stēd'man, Charles, American naval officer: b. Charleston, S. C., 24 Sept. 1811; d. 1890. He entered the navy as midshipman in 1828, was promoted lieutenant in 1841, and in the Mexican War was in command of the siege guns in the naval battery on shore during the bombardment of Vera Cruz. In 1855 he was appointed commander and sailed in the brig *Dolphin* in the Paraguay expedition. During the Civil War he remained loyal to the Union. In 1861 he commanded the railroad ferry steamer *Maryland* that conveyed General

The

Butler and the 8th Massachusetts Regiment from Havre de Grace to Annapolis; and later, after assisting Admiral Foote in organizing the naval forces along the Mississippi River, commanded the steamer *Bienville* at the capture of Port Royal, S. C. In the following year he commanded the *Paul Jones* during the engagement and capture of Fort McAllister and later operated on the Saint John's River, Florida. In September 1862 he was promoted captain, and in the *Powhatan* was engaged in the blockade of Charleston. With the steamer *Ticonderoga* he pursued the Confederate cruiser *Florida* to the coast of Brazil and took part in the two attacks on Fort Fisher in 1864. In 1865 he commanded the Mediterranean squadron and in 1866 he was promoted commodore and had charge of the Boston Navy Yard in 1869-72. He was appointed rear-admiral in 1871 and retired in 1873.

STEEDMAN, James Barrett, American soldier: b. Northumberland County, Pa., 30 July 1818; d. Toledo, Ohio, 18 Oct. 1883. He removed to Ohio in 1837 and entered the legislature of that State in 1843. In 1851 he was appointed by President Buchanan public printer at Washington, and at the opening of the Civil War became colonel of the 4th Ohio Regiment and fought in western Virginia and Kentucky in 1861-62. In July 1863, having already been promoted brigadier-general, he was placed in command of the first division of the reserve corps of the Army of the Cumberland and for his services at Chicamauga was promoted major-general 24 April 1864. He took part in the Atlanta campaign; defeated Gen. Joseph Wheeler's cavalry in June 1864 and served with General Thomas at Nashville while Sherman was making his march to the sea. He resigned from the army in 1866, retiring with the rank of major-general of volunteers. He was made provisional governor of Georgia, but resigned and received the appointment of collector of internal revenue at New Orleans. He subsequently became chief of police of Toledo and editor of the *Weekly Ohio Democrat*. In 1887 a monument was erected to his memory in Toledo.

STEEL. Before the introduction of the modern methods of steel making in the middle of the 19th century the name of steel was applied only to iron containing a sufficient percentage of carbon to become intensely hard on rapid cooling (quenching) from a red heat or higher temperature. The invention of the Bessemer and Open Hearth processes, however, by which it is possible to produce, in a molten condition, iron containing any proportion of carbon from a trace to 2 per cent or more, made a revision of the nomenclature necessary. The name of steel is now very generally applied to any iron obtained in a liquid state, provided it is malleable, regardless of the percentage of carbon it may contain and regardless, therefore, of whether it possesses or not the property of becoming hard on quenching. All malleable products manufactured by the Bessemer or Open Hearth processes are consequently classified as steel although some of them may contain but a mere trace of carbon and be as soft and as deprived of hardening power as wrought iron. Iron products which are obtained in a molten condition but which are not malleable,

owing generally to too high a percentage of carbon, are classified as cast iron. Iron products which are malleable but obtained in a pasty state are classified as wrought iron. This nomenclature necessarily leaves out of consideration blister steel (also called cemented or converted steel, and by the English blister bar) which is obtained by introducing carbon (the cementation process) at a high temperature but below the melting point, into bars of wrought iron. Ingot iron (obsolete) was a term applied to steel containing too little carbon to be usefully hardened. Plated bar is blister steel in the form of bars obtained through rolling or forging while hot. Shear steel is steel obtained through rolling or forging piles or fagots of plated or blister bars. After one such operation it is known as single-shear steel. The piling and forging of bars of single-shear steel yields double-shear steel. Bessemer, Open Hearth, crucible, electric steels, etc., are steels made respectively by the Bessemer, Open Hearth, crucible, electric, etc., processes. Crucible steel is sometimes called cast steel. All steels, however, are initially cast. Eutectoid steel is steel containing in the vicinity of 0.90 per cent carbon. Hypo-eutectoid steel is steel containing less than 0.90 per cent carbon, while hyper-eutectoid steel is steel containing more than 0.90 per cent carbon (see IRON AND STEEL, METALLOGRAPHY or). Acid steel is steel made by Bessemer or Open Hearth processes when an acid (silicious) lining is used. Basic steel is steel made by the same processes when a basic lining is used. Low phosphorus pig iron must be used for the manufacture of steel by an acid process whereas by a basic process high phosphorus pig iron may be used. Alloy or special steels are steels containing a sufficient percentage of one or more special elements to cause some of its properties to be deeply modified. The alloying elements most commonly used are nickel, chromium, tungsten, molybdenum, vanadium, manganese and silicon, hence the names of nickel steel, nickel-chromium steel, manganese steel, etc. By opposition steels which do not contain appreciable quantities of these elements are sometimes termed carbon steels. High-speed steel is an alloy steel generally containing large proportions of tungsten and chromium (sometimes also molybdenum and vanadium) and which after suitable heat treatment is so resistant to wear by abrasion that it can be used as cutting tools under such severe conditions that the cutting edge of the tool may be heated to a red heat by the heat generated in cutting and still retain its cutting properties. This makes high speed cutting possible, hence the name of the steel.

Iron and carbon are the essential elements of all ordinary (carbon) steels. The carbon content may vary from a mere trace (a few hundredths of 1 per cent to some 1.5 per cent). With much larger proportions of carbon the metal ceases to be malleable and is no longer, therefore, classified as steel. Manganese is a necessary element of all steels, its introduction in the process of manufacture being necessary to obtain good forgeability. It is generally present in amounts varying between 0.1 to 1 per cent. Sulphur and phosphorus are unavoidable impurities. No steel of good quality should contain more than 0.1 per cent of either

of these, while high grade steels should contain much smaller proportions. Silicon is also always unavoidably present, varying in amount between 0.1 per cent or less to some 0.3 or 0.4 per cent.

Assuming ordinary carbon steel to be in the annealed condition, i.e., having been slowly cooled from a red heat or higher temperature, as the carbon increases to 0.90 per cent the tensile strength of the metal increases from some 50,000 to 125,000 pounds per square inch, the elastic limit remaining equal to not less than one-half the tensile strength. With further increase of carbon the tensile strength decreases while the elastic limit continues to increase. The elongation which measures the ductility of the metal decreases with the carbon content from some 25 or 30 per cent in steel containing very little carbon down to some 5 per cent in very highly carburized steel. The hardness of the metal increases continuously with the carbon content while the hardening power reaches its maximum at about 0.90 per cent carbon. Very low carbon steel can be readily welded but as the percentage of carbon increases the difficulty of welding increases rapidly. Carbon lowers appreciably the melting point; while low carbon steel melts slightly below 1,500° C., steel containing 1 per cent carbon melts in the vicinity of 1,300° C. Through suitable mechanical and heat treatments the physical properties of steel can be deeply altered. Mechanical work performed while the metal is red or white hot increases its physical soundness and generally raises its strength and elastic limit. Mechanical work performed while the metal is cold greatly increases its tensile strength and elastic limit as well as its hardness, but decreases its ductility, eventually causing brittleness. The heat treatment generally applied to steel may consist (1) in annealing, i.e., in cooling slowly from a high temperature when it is desired to remove existing stresses, to produce softness and ductility, but necessarily at the expense of strength and elastic limit; (2) in hardening, i.e., in cooling quickly (quenching) from a high temperature followed generally by reheating (tempering) to a temperature seldom exceeding 400° C. when it is desired to produce implements of very great hardness, but necessarily lacking in ductility to the point of being actually brittle and (3) in hardening followed by reheating to a temperature generally exceeding 400° C. and which may be as high as 700° C. when it is desired to obtain great strength and elastic limit combined with a fair amount of ductility according to requirements.

ALBERT SAUVEUR,
Professor of Metallurgy, Harvard University.

STEEL, THE BESSEMER PROCESS.

The Bessemer process is employed to manufacture from the crude product of the blast furnace a comparatively low grade of steel, which is at the same time better suited for certain purposes than that manufactured by any other process. It does not seek to make high-grade tool steel or steel castings, but a cheaper grade, for which there is an immense demand, for instance, steel rails and structural shapes. It occupies a field in which it is and probably always will be supreme, so long as the supply of suitable

raw material lasts. Many modifications of the Bessemer process have been introduced, most of which have not met with approval, but one or two have become commercially recognized, such as the Clapp-Griffiths, the Robert and the Tropenas processes. These latter by variations in the method of applying the blast, or by modifications in the *modus operandi*, have made changes in the resulting product so that it may be successfully applied to the manufacture of castings, etc., but they are all essentially Bessemer converters. Further notes on these processes will appear later in this article.

To get a fair idea of the revolutionary nature of Bessemer's invention mention must be made of the fact that before his time steel, on account of the difficulty of its manufacture, was in use for practically little else but cutlery, springs and the small parts of machines. It had to be made in crucibles by melting cemented bar or "blister steel," itself the result of a long and costly operation on Swedish iron in a cementation furnace. A steel rail, building or bridge was unthought of. Everything was wrought iron, made at great expenditure of time and human energy in the puddling furnace or charcoal bloomery.

The story of Bessemer's discovery is of unusual interest. Experiments had been made from time to time to improve iron castings by the addition of wrought-iron scrap to pig iron in a cupola, and Bessemer had achieved more success than his contemporaries by the use of a reverberatory furnace instead of a cupola, into which he had introduced great improvements such as a hollow bridge wall through which jets of air were forced, giving a higher temperature, enabling him to fuse more steel in the bath of cast iron. How he came to discover that great principle on which all air-blast processes of steelmaking are based is best told in his own words. In connection with the description of some experiments with his forced draft reverberatory furnace he says: "Some pieces of pig iron on one side of the furnace attracted my attention by remaining unmelted in the great heat of the furnace, and I turned on a little more air through the fire bridge with the intention of increasing the combustion. On again opening the furnace door, after an interval of half an hour, these two pieces of pig iron still remained unfused. I then took an iron bar with the intention of pushing them into the bath when I discovered that they were merely thin shells of decarburized iron showing that atmospheric air alone was capable of wholly decarburizing gray pig iron and converting it into malleable iron without puddling or any other manipulation. Thus another direction was given to my thoughts, and after due deliberation I became convinced that if air could be brought into contact with a sufficiently extensive surface of molten crude iron it would be rapidly converted into malleable iron."

With great enthusiasm Bessemer proceeded to the next step, namely, the experimental test of his conviction. He procured a crucible having a perforated cover and a pipe of refractory material passing through the lid, connected to a blast supply. A small quantity of cast iron was melted in the crucible and while still in the furnace a current of air was passed through

it. After 30 minutes blowing the contents of the crucible were found to be soft malleable iron. The next thing to be determined was whether the chemical reactions caused by the blowing would generate sufficient heat to keep the contents of the crucible liquid without any additional heat being applied from outside. This seemed a preposterous idea—that blowing air into molten iron should only not solidify it in a short time, but actually increase its temperature very materially. But Bessemer was confident it would be so and immediately set about the construction of a converter. The first converter was about four feet in height, cylindrical, having a flat top with a circular opening, and six horizontal tuyeres around the bottom fed by a circular blast pipe. Its capacity was about 700 weight of iron, which was introduced by a sort of funnel in the side after the blast was turned on. The first blow was full of surprises, for what took place could be readily seen, whereas in the former experiments in the crucible the entire apparatus was out of sight. For the first few minutes sparks and smoke were emitted from the converter, but then a flame burst forth, which increased in violence so that no one could go near the converter. Then the flame died down and the metal was tapped out through a hole in the bottom of the converter, and found to be malleable. The possibilities of the process were now demonstrated beyond the slightest doubt, but prodigious labors were yet to be undertaken in order to make it mechanically perfect. The chief difficulties were that during the operation large quantities of slag and some drops of iron were blown out of the converter, and that the blast had to be kept on during the whole time of introducing the charge and also tapping it out when converted. Many changes were made in the interior shape to obviate the first. The height was increased and a double dome-shaped top added with the idea that any projections of slag and iron would strike the dome and drop back into the converter. This was fairly successful and was the type of converter used in the first public exhibition of the process. In order to overcome the necessity of keeping up the blast while filling and emptying the converter the shape which is so well known to-day was evolved after a great many changes and experiments. It had to be a movable vessel, in order to bring the metal away from the tuyeres and permit of shutting off the blast, and so a shape somewhat oval, and with a mouth inclined to one side at an angle, the whole mounted on trunnions, became the standard Bessemer converter. Other vast improvements came quickly, the hydraulically driven rack and pinion to rotate the converter, the hydraulic crane for handling the ladle and the casting pit for handling of ingots and molds. One of the difficulties encountered was the mixing of the slag with the iron, and this was overcome by providing a ladle having an opening at the bottom which was closed by a refractory stopper attached to a rod. The iron was run into the ladle and the stopper held in position till it was full. Then as the slag floated the stopper was withdrawn, allowing perfectly clean metal to run into the ingot molds.

The Bessemer process has another peculiar and romantic feature in its history in that it has

been twice invented. When he took out United States patents in 1856 Bessemer was confronted at once by a priority of claim to invention by William Kelly. The contention was sustained in the United States courts and Kelly was granted a patent. It is now not doubted that while the two men independently and separately discovered the principle, Kelly was ahead of Bessemer some eight or nine years in his discovery. Kelly was in the iron business in Eddyville, Ky., in 1846, refining iron in an old-fashioned refinery, to make kettles used in the manufacture of sugar. He was an inventive genius, but a poor business man. An inspiration came to him one day while watching the progress of his refinery, on noticing that at a certain place where the blast of air happened to play on the molten iron direct without the

Modern Rotary Converter.

intervention of any fuel, it became white hot and boiled violently. He immediately realized the revolutionary nature of his discovery and his knowledge of metallurgy easily furnished him with the explanation, namely, that the carbon content of the iron was acting as fuel, and by its combustion increasing the temperature of the iron. It was later discovered that the largest addition of heat arose from the oxidation of the silicon content, and that where less than one per cent of silicon exists in the iron the Bessemer process fails. On speaking of his hopes he was met with derision, but proceeded to make a public demonstration which convinced all who saw it. But, as with nearly all important dis-

coveries, there was a hard battle ahead of Kelly. There is always a prejudice against revolutionary discoveries, and Kelly's customers refused to accept iron refined by the new method even though it passed the customary tests. His financial backing was also withdrawn, but Kelly could not be extinguished. How he persevered with his process when experiment after experiment failed, how he worked secretly in the forest, and finally got permission from the Cambria Iron Works to erect a converter (the eighth he had constructed) in their works, and how after a disastrous commencement success was finally achieved, are familiar stories. Kelly was recognized as the inventor of the Bessemer process, and while Bessemer's patents were refused renewal, Kelly's were renewed. He died in 1888.

The Bessemer Process To-Day.—In modern American practice the pig iron is sometimes used direct in a fluid condition from the blast furnace and sometimes remelted in cupolas. Rapid working is the object aimed at so as to avoid loss of heat by radiation, and permit of the use of lower silicon in the pig iron. To-day but little more than 1 per cent of silicon is permitted in the charge and the blow is made in from 9 to 12 minutes. With a larger proportion of silicon the blow is unduly prolonged. Even with this comparatively low content of silicon the blows are sometimes too hot and steel scrap has to be added in the converter during the blow to cool it off. In place of scrap a jet of steam is sometimes turned on. As regards the capacity of the converter anything less than 10 tons is considered a small converter and the usual amount treated at one time is from 10 to 20 tons. Two types of the Bessemer process are in use, known respectively as the acid process and the basic process. The difference lies in the character of the lining with which the converter is fitted. In the first named type this lining is of acid material, chiefly silica (held together with fire-clay); and in the second type it is of basic quality, generally calcined dolomite, held together with a small proportion of tar. In the latter case a percentage of lime is added to the charge before the blowing begins—the purpose being the formation with the silica of a basic slag which does not attack the lining.

In the acid process the sulphur and phosphorus elements of the iron are not removed, the acid slag refusing to dissolve them. It is imperative, therefore, that iron selected for the acid process should contain less than .10 per cent of phosphorus and less than .08 per cent of sulphur in order to yield a grade of Bessemer steel acceptable to the market. In the basic process the oxidized silicon is readily absorbed by the basic slag, and hence is more quickly removed than it is in the acid process. The carbon ingredient is next eliminated; and following that condition the phosphorus and a part of the sulphur are absorbed by the basic lime slag. The basic process is most largely in use in regions where the phosphorus content of the iron is large—particularly in Germany and Great Britain. In the United States the acid process prevails almost universally. The lining generally consists of brick, sand or stone and the walls are lined to a thickness of about one foot. The bottom section of the

converter containing the tuyeres is separate from the main section and is about 26 inches thick on account of the great amount of corrosion that takes place there and each vessel has a number of extra bottoms so that they can be quickly changed when burned out. The diameter of the tuyeres is about half an inch. The pressure of blast varies from 30 to 10 pounds, the former being used at the commencement of the blow and the latter being the lowest it would ever be safe to reduce it to, and this only when the blow is particularly hot or the projections of slag excessive. Sufficient air must always be kept on to support the iron and prevent it running into the tuyeres and wind box. The converters are rotated to suit the exigencies of blowing, and receiving or pouring the metal, by means of a pinion attached to the trunnion, and a hydraulically driven rack. The illustrations to this article give a good idea of the development of the converter from the earliest type.

The Clapp-Griffiths Bessemer.—This process, which is now practically obsolete, was one of the earliest types of Baby Bessemer converters. Its capacity was from two to three tons. A stationary side-blown converter was used, having a slag spout at one side from which the slag poured during the boil. The converter was in two sections, being jointed on a line above the tuyeres and the bottom section was handled and put in place on a car which could be lifted by a hydraulic ram. The only original feature of the converter was the slag spout, and the benefit derived from its use was always problematical. It was claimed that the steel made in this converter, even though high in phosphorus, was vastly superior to that made in ordinary converters. This claim was of course not substantiated.

The Robert Process.—In this process a rotary converter was used with horizontal tuyeres placed tangentially, in order to impart a rotary motion to the metal. The tuyeres were submerged, but near to the surface of the bath. Whilst the loss was greater than in the ordinary vessel, a hotter steel was made, which was suitable for steel castings, and for this purpose it was almost exclusively used.

The Tropenas Process.—This has been by far the most successful development of the Bessemer process for casting work, introducing the idea that the violent mechanical disturbance of the bath is unnecessary and that the more tranquil the bath is the purer, sounder and better will be the steel. A rotary, side blown converter of two tons capacity is used, and the tuyeres are arranged in a symmetrical position from the centre tuyere in order that any tendency to stirring or rotation may be neutralized. The tuyers, moreover, are never beneath the surface of the metal, though they approach it very closely. A second row of tuyeres is placed a few inches higher than and parallel with the lower tuyeres, and when the carbon flame appears these tuyeres are opened, admitting air to complete the combustion of carbon from CO to CO₂. The result of this is to increase the temperature of the bath by radiation. A high silicon, high manganese mixture is used in the converter, and results in exceedingly hot and fluid steel, which can be car-

ried around in hand ladles and poured into very small and complicated shapes.

When the blast is first started the surface only of the metal is oxidized, three pounds pressure of air being used, and by dilution and change of specific gravity a fresh surface is constantly presented to the action of the blast without any mechanical disturbance whatever. In this way the possibility of occluded gases is reduced to a minimum, no more air being introduced than is necessary for the chemical reaction. The fact remains, however, that for casting basic open hearth steel is greatly preferred.

The Roll of Honor.—The history of the development of the Bessemer process in the United States is the history of a company of the brightest minds this country has produced. There is no doubt that the Bessemer process is worked more perfectly in America than elsewhere, and the credit must be given to those brilliant men who in the early days gave their great intellects to its problems and overcame them. The most important work has been done by A. L. Holley, John and George Fritz, William R. Jones and Robert W. Hunt. To Alexander Lyman Holley one of, if not the foremost American engineers, were granted 10 patents in connection with the Bessemer process alone, some of them being raised converters, hydraulic cranes, accumulating ladles and converter bottoms. Holley investigated the Bessemer process in England in 1863 and realizing its possibilities and also its defects obtained the only American license, and set to work to perfect its machinery. The latest and most important of the modern improvements is the Jones metal mixer, which is a large storage receiver in which the various quantities of iron direct from the blast furnace are stored and equalized, so that the silicon is uniform in the converter. One of the most important links in this perfectly welded chain was the work of Robert Mushet, who developed the method of recarburizing the iron after blowing in the converter. The Swedish method of checking the blowing when the carbon had been reduced to the proper percentage proved too slow and uncertain. Mushet's plan was to burn out all the carbon and restore a right proportion by the addition of a quantity of melted spiegeleisen (about 10 per cent) after the blow. Without his method the Bessemer process could not have been a commercial success. Considerable trouble was caused in the early days by the conflict of the Bessemer and Kelly patents. The Winslow, Griswold and Holley Company at Troy had control of the Bessemer patents covering the important and essential machinery, and the owners of the Kelly and Mushet patents could not operate without the use of this machinery. In fact each side was necessary to the other and naturally this resulted in an agreement by which a joint-stock company of all the pneumatic steel manufacturers was made. All the patents on these processes have now expired. According to the 1914 census of manufactures there were in the United States in that year 9,146 plants engaged in the manufacture of Bessemer steel. Their combined product was 6,219,304 tons of ingot steel and 43,437 tons of castings. The decline in the use of Bessemer steel in favor of open hearth steel is

markedly indicated by the decrease of nearly 3,000,000 tons in the annual production for the census period 1909-14 for the former and an equal gain for the latter. The production of open hearth steel in 1914 was over 17,000,000 tons—nearly three times that of the Bessemer product. See **STEEL.—OPEN HEARTH MANUFACTURE.** Consult Hall, J. H., 'The Steel Foundry' (New York 1914); Harbord, F. W., and Hall, J. W., 'The Metallurgy of Steel' (London 1918); Stoughton, B., 'The Metallurgy of Iron and Steel' (New York 1913).

ARTHUR SIMONSON,

Metallurgical Engineer, Philadelphia, Pa.

STEEL, ELECTRICAL PROCESSES OF MANUFACTURE. Electrometallurgical processes for the manufacture of pig iron, steel and ferro-alloys, have received profound attention from a commercial point of view during the years of this century. In fact, a commercial production of electric steels seems to coincide almost exactly with the opening of the 20th century, for we have it as a matter of record that three days before its beginning Heroult delivered to Messrs. Schneider and Company, Creusot, France, a carload of electric steel bars. This is the first record we have of a commercial sale and delivery of such steel. Experiments were made and basic patents covering different processes were taken out during the closing years of the 19th century. It is over 40 years, however, since Sir William Siemens constructed and patented an electric arc furnace which would melt steel. It is not recorded that he believed this laboratory furnace was the beginning of the new industry, but whether he thought so or not he stated very clearly the reasons why electric furnaces should be superior to other furnaces where the product is in contact with the products of combustion of carbonaceous fuel. The advantages of electric melting as stated by Siemens are, first, the degree of temperature is theoretically unlimited; second, the fusion is effected in a perfectly neutral atmosphere; third, the operation can be carried on in a laboratory without much preparation and under the eye of the operator; fourth, the limit of heat practically obtainable with the use of ordinary refractory material is very high, because in the electric furnace the fusing material is at a higher temperature than the crucible, whereas in ordinary fusion the temperature of the crucible exceeds that of the material fused within it. In short, he says that the function of electric melting is to "effect such reactions and decompositions as require for their accomplishment an intense degree of heat, coupled with freedom from such disturbing influences as are inseparable from a furnace worked by the combustion of carbonaceous materials." The soundness of these conclusions as applied to commercial conditions have been amply confirmed during the past decade. It seems like the fulfilment of prophecy, for they were overlooked and all but forgotten for nearly a generation until there arose a group of engineers and inventors in several European countries during the closing years of the last century who perfected various processes for doing in the mills what Siemens had done in the laboratory. The enthusiastic claims of these inventors were not received

with much interest by the steel men, but the Canadian government displayed commendable foresight when it appointed a commission in 1903 to investigate these processes at first hand in Europe, and in their report in 1904 Professor Harbord, the metallurgist of the commission, stated first "that steel equal in all respects to the best Sheffield crucible steel could be produced either by the Kjellin, Heroult or Keller processes at a cost considerably less than the cost of producing high class crucible steel," and second, "at present structural steel, to compete with Siemens or Bessemer steel, cannot be economically produced in the electrical furnaces, and such furnaces can be used commercially for the production of only very high class steel for special purposes." Even this opinion of a competent observer was not sufficient to overcome the conservatism of the crucible steel makers. The venerable crucible process had withstood the competition of Bessemer steel and of acid and basic open hearth steel, and it was only natural that the new arrival should be viewed with distrust.

At the time of this report the writer found it very difficult to accept Harbord's first conclusion except in so far as it applied to the induction type of furnace, in which at that time no purification of the charge was attempted, and to make a good steel one started with selected raw materials just as in crucible melting. The combination of melting and refining in one operation did not appear promising, and such samples of steel as came under examination, both foreign and domestic, did not tend to change this opinion. Metallurgically considered, electric furnaces are of two kinds. First, the early melting furnaces analogous to the crucible steel process—for example, the earlier Girod or the Colby and Kjellin induction furnaces; and second, smelting or refining furnaces, such as the Keller or Heroult furnaces for either pig iron or steel. In furnaces of the melting type we must start with the best raw materials if we wish to produce the best steel. Furnaces of the second type may be used (a) for the electric refining of pig iron direct from the blast furnace; (b) for melting and refining cold pig iron and scrap; (c) for the direct reduction of iron from its ores with or without subsequent refining to produce steel; (d) the electric refining furnace such as the Heroult, may be used as an adjunct to the open hearth or Bessemer process, in which the preliminary melting and refining is done. Electrically considered, these furnaces include (a) arc furnaces, e.g., the Stassano process; (b) arc-resistance, e.g., Heroult steel process; (c) resistance furnaces, e.g., the Keller, Harmet and Heroult pig-iron furnaces, in all of which there is a movable carbon electrode and the hearth constitutes a fixed electrode. These furnaces are especially suited to the reduction of iron ore, the charge of ore, lime and coke constituting a resistance conductor between the movable electrode and the fixed electrode. In the Girod process a current is passed through the melt itself, making use of the Joule effect. In the Girod crucible process we have what may be called a furnace of the superficial resistance type. The current does not pass through the charge itself. The furnace consists of a crucible of refractory materials surrounded by a

granular carbon resistance material to which the current is conveyed by solid carbon conductors, and the whole device is enclosed in a refractory chamber of non-conducting materials for thermal and electrical insulation; (d) the induction furnace invention is due to E. A. Colby, but Kjellin, Schneider and others employed the same principle, in that the heating current is an induced one, generated in an annular bath of metal constituting a single-turn-secondary of a step-down transformer. In the original Colby patents the primary windings of the transformer surrounded both the electro-magnet and the crucible itself. In the Kjellin process the primary winding is close to one leg of the electro-magnet and both are surrounded by the single-turn-secondary or crucible itself. It would appear that there might be an advantage in dividing the primary winding into two parts, one within and one without the crucible-secondary, in other words, in combining the Colby and Kjellin constructions in the same furnace. In the limited space of this article only a few typical processes can be described illustrating some of the above-mentioned general principles of construction. The variety of details of construction are very numerous, but the underlying principles are not so numerous; in fact, while so-called new processes have been introduced frequently during the past 15 years, they do not constitute essentially new discoveries, but differ only in details of application of the electric heating and of furnace construction.

Before describing a few of the processes it may be said that in the earlier days of electric steel furnaces it was considered that they could only be installed in places most favorably located for a cheap supply of power, or in places where metallurgical fuel, such as coal and coke, was extremely scarce and high priced. The earlier furnaces were all of the single-phase type, and in the case of those employing electrodes only one or two electrodes were used. About 10 years ago three-phase furnaces with three electrodes came into use, and since that time furnaces with from four to six electrodes have been produced in the larger sizes. The cheapening of power costs in many localities has brought about a much more general introduction of these furnaces than was contemplated even by their inventors. Another early idea in regard to electric furnaces operation was that they could only be used commercially for refining material previously melted in the open hearth or the Bessemer. The first installation in the United States, which was made at the plant of the Halcomb Steel Company, was of this type, and the electric furnace, which was of four gross ton capacity, was used for refining material melted in a 20-ton basic open hearth furnace. This installation is still in use after 13 years of continuous service. An identical installation was started in Germany at almost the same time. To-day furnaces operated on cold charges are much more numerous than those employing the original duplex process, and they are located in places that formerly would have been thought unsuitable for such installations.

The Stassano Process.—In the Stassano furnace the heat is radiated from one or more pairs of large carbon electrodes placed above

the charge and in the top of the furnace. The furnace is of the arc type, and, as the electrodes are not in contact with the material that is to be melted, it is plain that no impurities are introduced into the melt from the electrodes themselves. Either iron or steel may be produced, depending upon the mixture used. With the earlier furnaces of this type the hearth

large electrodes pass through the roof of the furnace. In the single-phase furnace, such as was first used exclusively, the current passes down one of these electrodes, crosses a narrow air gap through the melt, and is then conducted back through the slag and another air gap to the second electrode. Alternating current of about 100 volts is used. The

HEROULT STEEL FURNACE.—A, lip of furnace; H, dolomite brick, lining the metal shell; K, crushed dolomite constituting the hearth; E, one of the electrodes; R, S, T, P, Z parts of device for regulating the position of the electrodes.

rotated during the operation at a small angle to the vertical, facilitating the mixture of the ingredients and the reactions taking place in them. This process is still in use in Italy with both rotating and stationary hearths. Its use has not been adopted to any very great extent in other countries, and some of the installations that were made in this country have been abandoned. It was found that the arc, placed so high above the charge, produced an excessive heating of the refractories of the roof, and that the expense for upkeep was high. The furnace is capable, however, of producing high-quality steel.

Heroult Process.—This process, as applied to the production of steel, makes use of an arc-resistance tilting furnace, usually basic lined with dolomite or magnesite. Two or more

width of the air gap is automatically regulated by very ingenious devices which automatically raise or lower the electrode as the resistance in the circuit varies. Tool steel, or structural materials, and especially alloy steels, can be made by this process in this furnace either from a charge of cold materials or from a liquid charge previously melted in some other furnace. The charge may consist of miscellaneous scrap, ore and lime, and usually some fluor-spar, sand and lime are used for the preparation of slags toward the end of the process. When it is desired to remove both sulphur and phosphorus from the charge it is customary to rake off the first slag formed during the melting-down period, and with it goes most of the phosphorus. The operation during this period is oxidizing. After the phosphorus slag

is removed a second slag, usually known as a "carbide slag," is formed, and under reducing conditions in the furnace the sulphur is very largely eliminated. In this particular the electric processes of several types are far superior to any other processes for removing sulphur. When such furnaces are used in conjunction with the basic open hearth furnace, the burden of dephosphorizing is borne by the basic open hearth and desulphurizing and deoxidizing only are done in the electric furnace, and the operation is carried out entirely under reducing conditions.

made by the Canadian commission, by Dr. V. Engelhardt and by the writer, during the earlier years of its operation. The furnace, as described by Dr. Haanel, constitutes a step-down transformer. A primary coil of insulated wire is wound about one leg of the magnetic circuit. The secondary is formed by the charge in an annular groove, also surrounding the same leg of the magnetic circuit. In the original Kjellin furnace at Gysinge, Sweden, the primary alternating current is delivered at 90 volts and 3,000 amperes. The secondary current induced in the charge itself is of low

A, is just above the primary coil; B, iron core or magnetic circuit; and C, the bath (secondary circuit). The advantages of this furnace are that it can be tipped over the lip, or from the taphole, and can easily be repaired and relined when necessary.

Colby and Kjellin Processes.—The inventor of the induction furnace was Mr. Edward A. Colby, an American. It does not appear, however, that at the time of taking out his patents in 1890 he had any idea that the process might be used on a large scale for steel melting. Ten years later Kjellin, in Sweden, employed the principle of induction to the construction of electrical furnaces for steel melting, and since the results of these later experiments have been made public Colby has also designed a furnace for similar use. The Kjellin process was put into actual service in Sweden about 1900, producing a merchantable product, mostly tool steel, and has been made the subject of many careful investigations. This process naturally attracted the attention of makers of high-grade steels as the nearest substitute for the old process of crucible melting. The furnace was studied in operation, and careful investigations of the product were

potential, and the conversion of electric energy into heat takes place in the substance of the charge itself. The furnace may be either acid or basic lined, but the latter is most used, the lining constituting the annular groove or crucible, being usually made of magnesite. The furnace may be either tilting or stationary. No attempt was made at purification of the materials used, but carefully selected raw materials, well melted, gave an excellent steel, the analysis of which was nearly the mean of the constituent materials of the mixture. This, of course, is a more expensive way of producing tool steel than by refining processes, but it is the surest way, and processes depending upon refining methods can never be as certain in their results as the crucible or the induction process, in which raw materials of known impurity are employed. Larger furnaces of the induction type were later produced in Germany, in which by a special arrangement

of the hearth refining was possible, but in both the simpler and these more complicated furnaces the question of repair of linings was very serious, and it can scarcely be considered that they have been a commercial success. Some very large ones were installed in this country, but it is understood that they have been abandoned as uncommercial. One electrical disadvantage is that these furnaces for best operation require a current of unusually low frequency. The modified Kjellin furnace, adapted to refining, is known as the Rochling-Rodenhauser furnace. The induction furnace can operate upon two kinds of mixtures: first, pig iron or scrap, and second, pig iron, scrap and ore briquettes.

Conclusions.—Of the many other processes two may be mentioned which employ the principle of bottom electrodes. The Girod furnace makes use of water-cooled metallic electrodes imbedded in the bottom lining of the furnace so that the current actually passes through the charge itself from top to bottom. The Greaves-Etchells furnace, a fairly modern English process, makes use of the principle of a conductive hearth itself, and no inserted electrodes are used. The entire bottom, after the furnace is once heated, becomes a resistance conductor and is supposed to produce beneficial results by heating the materials at the bottom of the charge more perfectly than can be done by an overhead arc furnace, and this advantage is supposed to be most marked in the manufacture of alloy steels, especially those of heavy metals, such as tungsten, which sink through the bath and are apt to lie on the bottom of the furnace without being entirely molten or absorbed by the charge itself. It is difficult to compare the various processes as to their efficiency. In the first place, at no one plant have all of them been tried under uniform conditions and skill of operation. There are so many variables entering into the matter that comparisons can be made only in one or more particulars. For example, the current consumption per ton of product can be readily compared, but unless the furnaces compared are operating under similar conditions, and on a similar product, the figures are quite valueless. Moreover, in melting a similar quality one furnace may require more current than another, simply because the melter refines his steel more perfectly and the kilowatts used may make the difference between well and poorly-melted steel. Other variables are the life of the roofs, bottoms, side walls and electrodes, the first cost of the furnace and the quality of construction, and, from the power-house point of view, simplicity and the cost of equipment must be considered, and this involves differences of phases, frequency, voltage and power factor. When all of these elements are considered, together with ease of operation, it is apparent that it is not simple to give off-hand judgment as to what furnace is best to use. The time is past when the electric current itself is supposed to confer any mysterious benefits upon the products, but its function is just as stated by Siemens 40 years ago. Various claims are made by inventors depending upon whether the current passes through the bath horizontally or vertically or is merely radiated to the surface. However, it should be remembered that at the temperature involved molecu-

lar mobility is very great, and solution and diffusion will take place satisfactorily if the total heat available is sufficient to maintain the entire contents of the bath perfectly fluid.

The electric processes under most careful handling are capable of producing steel approximately equal to crucible steel, but each process has its peculiar field, and while some crucible tonnage may be diverted to electric steel, yet it is more likely that electric steel will find its own market in the most exacting requirements of steel for structural and tensile properties, such as have come about almost simultaneously with the processes themselves, namely, for the automobile and airplane parts. Crucible steels for these purposes are not commercial because of the difficulty of making very low or medium carbon alloy steels in the crucible and the tonnage demand is far beyond what could be met by the crucible process. The electric furnace was apparently invented to meet a new demand rather than to replace an old process. As one writer has said, "The luxury of to-day is the necessity of to-morrow. Safety cannot be measured by price, and public opinion will more and more insistently call for the highest excellence in the automobile, the airplane and other forms of fabricated material."

There are now in use in the United States between 300 and 400 electric furnaces of various types, over half of them being of the Heroult design. There are probably as many furnaces altogether in Europe as there are in the United States. The introduction of the process was stimulated amazingly by war requirements for materials of unusually high grade, and in meeting these requirements the electric steel makers responded nobly in their contribution to the war program.

STEEL, EVOLUTION OF STEELMAKING PROCESSES. In prehistoric times the earth's inhabitants fashioned their im-

plements from flint. After a time, as the result of observation or chance, primitive men discovered that metals, such as copper and lead, could be obtained from certain earths or ores, and it was not long until they found that copper could be made harder by the addition of a little iron, arsenic or tin. That they ever actually hardened copper, in the sense that we harden steel for tools, is extremely improbable.

It is not easy to say whether the Bronze Age preceded the Iron Age or not, and if it did, by what period. Flint instruments and weapons are almost imperishable, bronze is very enduring, while iron rusts, and if buried in a damp place is wholly converted into hydrated oxide or carbonate of iron, soluble in waters containing much organic matter. For this reason iron relics of great age are scarce, while flint and bronze fill the museums. However, in certain ruins of the Swiss lake dwellings all three sorts of implements were found, flint, bronze and iron.

The use of iron is frequently mentioned in the early books of the Old Testament. The Egyptians were familiar with it at least 4,000 years ago. The Assyrians probably knew how to obtain iron from its ores and how to fashion it into saws, chisels, etc., at a still earlier date than the Egyptians. The various ages known as the Stone, Bronze and Iron ages are not fixed periods in the world's history, but are periods in the history and development of individual tribes and nations. For example, while at a period, say 1000 B.C., the Egyptians and Assyrians were making swords of iron (and a cross-cut two-handed saw of this period is in the British Museum) the Bronze Age existed in southern Europe, while in the northern and western Europe wood and stone implements were in general use. In India, China and Japan there is abundant evidence of the manufacture and use of iron at a very early period. In this very day there are tribes in central Africa which have but attained the degree of skill which we picture in our minds when the "Iron Age" is mentioned. They are making iron in a most primitive fashion and their methods may be the identical ones used thousands of years ago by the Assyrians. Their metallurgical skill is by no means slight, for they know how to smelt ores in a little cupola blown by a hand bellows, and to employ the right fluxes to obtain a product of remarkably good analysis. They use charcoal as fuel and the chunks of metal which they obtain by first smelting are sold to smiths who refine them still further by a sort of puddling process, and a tool made by this means gave, according to Bellamy and Harbord, the following excellent analysis: Carbon, 1.02; silicon, .026; sulphur, .006; phosphorus, .012; manganese, trace. There are evidences in Belgium of ancient iron workings dating from the Roman occupation, and they were famous armorers through many centuries. The skilled workmen of this country emigrated especially to England and Sweden and were the founders of the fine steel industries in those countries. Those who emigrated were the Walloon Belgians, and the exodus became so great that at one time it was stopped by law.

During the time of the Norman Conquest

and the Tudors, the manufacture of iron in Great Britain was an insignificant industry, and the chief supplies were imported from Belgium, and from Belgium came the invention which gave a great impulse to the iron and steel business, viz., the invention of the blast furnace. Prior to this invention iron was produced direct from ore in a crude form of hearth, the product being wrought iron or steel, which was obtained in a solid or pasty condition far from homogeneous in composition, and when large or intricate forms were desired they were made from these crude materials by laborious welding and forging methods. With the invention of larger and improved blast furnaces by the Belgians it was found that practically a new metal, fused cast iron, was at the disposal of the early metallurgist. Cast iron was made in Sussex as early as 1350, and the art of iron founding gradually grew and flourished in England and on the Continent, until in 1543 cast-iron cannon were made in England, and in 1595 these were made as heavy as three tons each. But cast iron was not only used for foundry purposes, for it was argued that if by one application of the purifying influence of fire the crude metal had been prepared from the ores, the second application of the same agency might convert it into a malleable product, and wrought iron was subsequently produced in small fineries, and from that day to this the blast furnace has been the first step in the manufacture of iron and steel. Much of this early wrought iron was delightfully low in sulphur and some other impurities, but at that time no means were known of reducing the phosphorus, and the amount of this element present in the product was due to the chance selection of the ore. There were no chemists in those days to say whether the iron contained phosphorus or not, and practical experience with the product in use was the only way of determining the merits of ores from various sources. It was soon discovered that wrought iron by long heating in contact with carbon absorbed some of that element and was thus converted into "cemented" or "blister steel." Blister steel when piled, welded and forged becomes "shear steel," and if shear steel is piled, welded and forged the product is known as "double shear." By this piling and welding operation, the carbon which is highest in the outer portions of the cemented bar becomes more uniformly distributed throughout the mass of steel. In 1781 Bergman, of Upsala, pointed out that it was carbon which determines the difference between wrought iron, steel and cast iron.

The early steel works were all located in the vicinity of great forests, for charcoal was the only fuel used. The works were also located near running streams, and water wheels were used to provide power for the blast, and for the first power hammers. There are many such still in use in Sheffield. In Queen Elizabeth's time the iron trade had become so great that the wholesale destruction of forests was stopped, and the position and number of iron works was limited by law. As the result of this legislation the iron trade languished until Dud Dudley, in 1620, or a little earlier, successfully used coal in the blast furnace. In his day 20 tons a week was a large output for a

blast furnace, while to-day the output of one of the blast furnaces at Homestead is nearly 5,000 tons per week. In primitive processes, the workers took advantage of natural draft and located their furnace on a windy hillside. Later, crude bellows were made from hides and still later a blowing arrangement operated by flowing water was invented. Not much real progress could be expected from such crude devices, and one of the first applications of the steam engine of Watt was running a blowing engine at the Carron Iron Works in 1760. It was not until 1730 that it occurred to Abraham Darby and his son to treat pit coal just as his charcoal burners treated wood. His idea, needless to say, was a good one, and coke was produced, which in turn was soon successfully used in the blast furnaces, and is at the present time the principal fuel used in blast furnace practice, although a few charcoal blast furnaces remain in America and are quite common in Sweden. The next great advance in the metallurgy of iron was that of Robert Huntsman, of Sheffield, who first produced crucible steel in the year 1740. As Dr. Percy says, referring to Huntsman: "Formerly, so far as I am aware, steel was never melted and cast after its production; indeed, by the founding and casting of steel after its production its heterogeneousness is remedied, and ingots of the metal can be produced perfectly homogeneous throughout, and for the practical solution of this problem we are indebted to Robert Huntsman, of Sheffield."

Huntsman was by trade a clockmaker, and no doubt had his troubles in attempting to make springs from the crude steel which was available in his time. It was to overcome this difficulty that he began experiments with a view to melting the cemented, or blister bar, of his day, to obtain a homogeneous product. A grandfather's clock, the pendulum rod and spring of which are supposed to have been made from the first cast steel produced by Huntsman, is still shown in Sheffield. Huntsman's chief difficulty in his investigations was to find the right kind of clay for making crucibles which would stand the intense heat of steel melting. His first crucibles were only 10 inches high, and held about 20 pounds of steel. Steel made by this process was of course expensive, and could only be used for edge tools, dies and drills, for which a great degree of hardness and fine polish was desired. The original business started by Robert Huntsman is still conducted by his lineal descendants of the fifth generation at the present time. See STEEL, MANUFACTURE OF CRUCIBLE.

The next great inventions which made for progress in the iron industry were those of Henry Cort (b. 1740; d. 1800), who first made use of grooved rolls in 1784, and in 1785 produced the dry puddling process. The invention of puddling was without doubt the foundation of Great Britain's commercial greatness during the century that followed. Prior to this time cast iron had been decarbonized in small hearths, very wasteful of fuel and labor, in which only 100 pounds could be treated at a time. Cort employed the reverberatory type of furnace, in which the metal was not in contact with the fuel, but was heated by the flame, which was caused to reverberate, or beat down

from the roof of the furnace. This process permitted the use of coal instead of charcoal, and allowed the use of 250- to 500-pound charges. The story of Cort's life is a very sad one, for through a dishonest partner, who died suddenly, his patents were seized to satisfy this partner's liabilities, and Cort died in poverty in 1800. Prominent treasury officials were implicated in this unjust treatment of Cort. Quite recently Americans have erected a bronze tablet to his memory in the little church in Homestead, in the churchyard of which his grave was located with difficulty.

The invention of the hot blast by J. B. Neilson, of Glasgow, in 1828, afforded the next great advance in the metallurgy of iron. In six months the fuel consumption per ton of product was reduced from somewhat over eight tons to a little over five tons, the blast being heated to 300° F. A few years later the blast was heated to 600° F. and the fuel consumption dropped from five and one-sixth to two and one-fourth tons. At the same time there was a great increase in output as well as decrease in fuel consumption and the production of pig iron in Scotland increased fivefold between 1830 and 1840, while the use of the hot blast became a general practice during that period. As was the case with Cort, so Neilson reaped almost no reward for his invention, although the wealth it conferred upon iron manufacturers could hardly be reckoned. The same was true of Heath, who in 1840 patented the use of manganese in steel. This conferred an incalculable benefit upon the manufacturers, but Heath died unrewarded after 15 years of litigation.

It was not until 20 years after the discovery of the value of the hot blast that Sir William Siemens introduced the system of regenerative gas firing—a system in which the waste products of combustion are employed to heat the incoming gas and air of a gas furnace or the blast of a blast furnace. The application of this principle of regenerative heating in the Cowper and Whitwell stoves effected a still further great saving in fuel in the blast furnace and at the same time increased the yield.

During more than one-half of the last century wrought and cast iron were the only materials available for structural and machine construction, boilers, engines, etc. Crucible steel owing to its high cost could not be used for any of these purposes. Such was the situation when Henry Bessemer gave to the world his wonderful invention. This was the real beginning of the modern age of steel in which we live. Prior to Bessemer's invention there is every reason to believe that William Kelly, an American, was working upon what may be called the "pneumatic process." According to a recent magazine writer, Kelly was experimenting with this process fully 10 years before the date of Bessemer's invention and had built seven stationary converters prior to 1856. His claim of priority of invention was allowed by the United States Patent Office. Nevertheless the process is universally known to-day as the Bessemer process and indeed there can be little doubt but that Bessemer made an independent discovery of the pneumatic process. Robert Hunt and James M. Swank both agree that for priority of invention William Kelly deserves all praise. See STEEL, THE BESSEMER PROCESS.

Although the first iron furnace in America was built in 1619, in Virginia, and the first blast furnace with forced blast dates from 1714, nevertheless the iron and steel business did not assume a large magnitude in the United States until the building of the Edgar Thompson furnaces in Pittsburgh, the first of which was blown in in 1879. In these furnaces American skill showed the world how to triple the weekly output and to cut the fuel cost in two. That is, while the best English and Scotch furnaces in 1880 produced from 400 to 800 tons of pig iron per week and required two tons of coke for one ton of pig, the Edgar Thompson furnaces between 1880 and 1885 produced from 2,000 to 2,500 tons per week and used only one ton of coke to one ton of pig. The coke in some cases fell as low as 1,882 pounds per ton of output. The ore used contained about 62 per cent of iron and the volume of air reached 25,000 cubic feet per minute, at a temperature of 1,000° to 1,100° F.

While we thus see that the modern steel industry is of such recent date, yet the inventions of the processes now used mainly, viz., the Bessemer (1856) and open-hearth (1861), for making steel, were relatively of long standing, and the gradual improvements in the processes themselves, their mechanical details and costs, and the gradual education of the large users of metals to employ steel in place of wrought iron and cast iron, gradually led up to the enormous demands of the last 30 years, to which the American manufacturers have responded so energetically.

Henry Bessemer was of a distinctly inventive turn of mind and had many useful inventions to his credit before he turned his attention to steelmaking. He gave considerable attention to the manufacture of projectiles during the Crimean War. The cast iron cannon of this time were seen to be unsuitable for Bessemer's powerful projectiles and he, therefore set about producing not only the projectiles, but a better material for making large guns. After many trials and discouragements he succeeded in producing steel from cast iron by blowing air through it to oxidize the impurities. His first experiments were performed in a crucible, and this being successful his next idea was to use several crucibles fed by a common air pipe. Later he adopted a large stationary converter about three feet in diameter and seven feet high and used 700-pound charges. The results were most astonishing, for Bessemer found that by the simple method of blowing air into fluid cast iron that the highest temperature then known in the arts was produced. The first formal announcement of his invention was made at the British Association for the Advancement of Science in 1856, the title of his paper being 'The Manufacture of Malleable Iron and Steel Without Fuel.' Great excitement followed the reading of this paper and the process was tried in many parts of England, but in many cases the results were anything but satisfactory. The steel produced was red short and cold short. The cause of the trouble was soon found to lie in the use of very impure pig irons running high in sulphur and phosphorus. The first converters were lined with acid or silicious materials, and little or no sulphur or phos-

phorus was eliminated. As long ago as 1856 Dr. Collyer writing of the effects of phosphorus and sulphur said: "The former I consider most pernicious of all. I would suggest, with due deference, that a stream of finely pulverized anhydrous lime be forced at a given time with the compressed air into the incandescent mass of iron. The lime having a great affinity for silica and phosphorus would form a silicate and phosphate of lime and be thrown off with the slag. By this contrivance I cannot conceive but that the phosphorus would be entirely got rid of." Here we see the "basic Bessemer" process clearly anticipated many years before it was actually successfully worked out and adopted (1871). The irregularity mentioned above was overcome by the use of selected pig irons, low in sulphur and phosphorus, and by the important discovery of Robert Mushet, viz., the addition of manganese to the metal in the ladle after the blow. The steel in the converter after the blow is dead soft, being nearly carbonless, and contains a good deal of dissolved oxide of iron, beside rather high sulphur and phosphorus. The addition of speiseisen or ferro-manganese corrects all of these troubles. It adds a certain amount of carbon to the steel, thereby increasing its strength and hardness; it deoxidizes the overblown metal and the residual manganese combines chemically with phosphorus and sulphur, some of the sulphide and phosphide being eliminated in the slag, and the rest being rendered relatively harmless by reason of its combining directly with the manganese. After these chemical difficulties with the process had been overcome, Bessemer and others turned their attention to the mechanical side of the question and produced the converter mounted on an axis, so that the vessel could be rotated or tipped down and the air-inlets or tuyeres could be thus brought either above or below the surface of the metal in the converter. This improvement rendered the charging or discharging of the metal much easier. Bessemer was more fortunate than all the other inventors previously mentioned in that he made a vast fortune out of his invention. As a matter of fact his invention was so complete in every way that the process stands to-day exactly as he originated it, excepting for minor details. Somewhat less than half of all the steel now produced is made in the Bessemer converters. What the invention of Bessemer steel meant to the world will be seen from a few illustrations.

Steel boiler plates were first used in 1860, and because of their much greater strength, permitted of steam pressure up to 80 pounds being used. This was a great advance in boiler-making. Three years later locomotive boilers were made of steel. But the greatest applications by far for steel were for steel rails and steel ships. The first steel rails were made in the year Bessemer steel was first described to the public. They lasted six years in a place where iron rails had to be replaced every three months. From that day to this the great bulk of steel rails has been made by the Bessemer process. In 1863 two small barges were built of steel, and a year later a steel vessel of 1,250 tons was built.

Basic Bessemer.—Many investigators tried to solve the problem of removing phosphorus

in the Bessemer blow, but it was not until the early 70's that Mr. Sidney Thomas came to the conclusion that its non-removal was due to the presence of a strongly acid slag, and obviously a basic slag could not be maintained in an acid lined vessel. After many failures Thomas and his cousin, Mr. Gilchrist, discovered that a lining of lime or dolomite could be made for the converter, using silicate of soda or clay as a binding material, and that additions of lime during the blow facilitated the removal of phosphorus and that an "after-blow" was necessary.

Open Hearth.—The next great advance in the metallurgy of steel was the development of the open-hearth process. (See STEEL, OPEN HEARTH MANUFACTURE). The prior discovery which led up to the open-hearth process was the invention of the regenerative furnace by Sir W. Siemens. William Siemens, a German by birth, had both a technical school and university education. His first visit to England was in 1843 for the purpose of introducing a process of electroplating, by means of which silver was deposited with a bright, smooth surface, rather than in the form of a crystalline deposit. The following year, 1844, he returned again to England and resided during the 40 more years of his useful life.

Siemens, profoundly impressed by the theory of the conservation of energy and with Joule's determination of the mechanical equivalent of heat, was ultimately led to the great discovery of the regenerative gas furnace. Then Siemens invented his gas producer, and with economical gas fuel the regenerative gas furnace was a great success. The first furnace on a commercial scale was used for glass melting in 1861, and a little later it was used for zinc distillation, heating and puddling furnaces, and for melting crucible steel. In this latter application it is used exclusively in America, while in England coke fires are still used for melting crucible steel. These are very wasteful of fuel, and possess not one single advantage over the Siemens producer and regenerative gas crucible melting furnace.

Siemens was not very successful in applying his invention to steel melting on the hearth of the furnace itself, and it was several years before any degree of success was attained in England, but meanwhile Messrs. P. and E. Martin, in France, taking Siemens' own drawings, erected a furnace in France and overcame the obstacles that had almost proved too much for Siemens. Thus originated the Siemens-Martin process, as it is universally known abroad; while in America it is usually merely designated as the open-hearth process.

Martin produced his steel from wrought iron scrap dissolved in cast iron on the hearth of Siemens' furnace, with the necessary recarbonization at the end of the process and the addition of manganese. This method is known as the "pig and scrap" method. Siemens meantime was working on a method now known as the "pig and ore" method, in which pig iron is decarbonized by the addition of ore, while scrap may or may not be used. It was not until 1868 that the open-hearth process became an assured success.

As with the case of the Bessemer process, so with the Siemens-Martin, the acid process

was the first to be employed. In fact Acid Bessemer and Acid Open-Hearth steel both antedate the basic Bessemer. Thomas and Gilchrist, who perfected the basic Bessemer process, also realized that the essential change necessary to dephosphorize was to substitute a basic lined furnace for the acid lining which had been previously used, and the maintenance of a basic slag during the operation by the use of lime.

Thomas announced the success of his experiments in 1878 before the Iron and Steel Institute, and although he announced that he had succeeded in removing from 20 to 99.9 per cent of the phosphorus from iron in the converter, and thus rendered available for steel-making mountains of ore the world over, which without dephosphorization were useless, his announcement attracted little attention, but before many years England was besieged with German, French, American and other metallurgists, anxious to learn about the epoch-making discovery,—the basic steel process. Germany profited particularly because of the large quantities of phosphoric ores which thus became a valuable asset.

In favor of the Bessemer process we may say that when steel of from .06 to .10 per cent phosphorus is wanted it is a cheaper process than open-hearth, but low phosphorus Bessemer requires a very careful selection of raw materials. Phosphorus and sulphur must be lower in the raw materials than is desired in the steel. A disadvantage of the Bessemer process is that the steel cannot be tested during the operation. Bessemer plants are suitable where tremendous tonnages of a rather cheap product are required. The open-hearth process gives a good outlet for steel scrap, billet ends, old rails, etc. The product is more reliable than Bessemer, and the low phosphorus open-hearth steels are much cheaper than low phosphorus Bessemer. The process allows more latitude in the selection of raw materials. Low or high sulphur pig can be used and both phosphorus and sulphur can be reduced. The steel can be tested chemically and physically during the operation, and whereas in Bessemer it is customary to continue the blow until all the carbon of the pig is oxidized, in the open-hearth process the decarbonization can be checked when it has gone far enough, or when the carbon desired in the product is reached.

As regards the quality of steels made by the various methods, it is undoubtedly true that even when the analyses are almost identical that crucible steel takes first place. Next in order comes open-hearth, and last place falls to Bessemer. As regards excellence of analysis, they usually stand in the same order, crucible being finest, open-hearth next and Bessemer last. Acid open-hearth, if the proper materials are used, i.e., if virtually a crucible mixture is melted in an acid open-hearth furnace, will be a most excellent material, but as actually made, acid open-hearth is usually very high in sulphur and phosphorus and much of it resembles a Bessemer analysis. In general then basic open-hearth takes next rank to crucible because of its low phosphorus and sulphur contents. In general, of two steels of identical analysis, acid and basic open-hearth, the former will show much the

higher tensile strength. Campbell has even constructed a formula for calculating tensile strength from the analysis, and in his formula it is assumed that each 1/100 per cent of carbon increases the tensile strength by 1,000 pounds in acid steel and only 770 pounds in basic. Each 1/100 per cent phosphorus exerts the same effect in either process and raises the tensile 1,000 pounds. One one-hundredth per cent manganese in low carbon acid steel raises the tensile 80 pounds and 130 pounds in basic, but the condition is reversed when the carbon is high and then the manganese raises the tensile by 400 pounds per 1/100 per cent in acid and only 250 pounds in basic. The effect of sulphur is very small.

As regards the tonnage production of steel we find that the most remarkable increase is in open-hearth steel. In 1917 the increased production of open-hearth steel over 1907 was over 200 per cent; and the total reached the impressive figure of 34,148,893 tons, or three times the production of 10 years ago.

The total production of open-hearth and Bessemer steel in 1896 was 5,250,000 tons, while in 1906 it was about 23,000,000, and in 1916 42,500,000 tons. In 1896 25 per cent of all steel produced was open-hearth and 75 per cent Bessemer, while in 1917 there was three and one-half times as much open-hearth steel made as there was Bessemer.

One must not imagine from these figures that the production of Bessemer is declining materially. The facts are that Bessemer production is about at a standstill while the gain is in the making of open-hearth steel. The basic open-hearth process has made much more rapid gains than the acid. In 1917 about one-sixteenth of the open-hearth steel was of acid manufacture. Nevertheless that was the biggest year by a considerable margin the country has ever had in the manufacture of acid steel.

Bessemer steel still holds its own to a considerable extent for rails, although open-hearth steel is making great progress in this direction and is more largely used than Bessemer for ordinary structural purposes. Of the Bessemer steel made in the United States every bit is acid. Of the acid open-hearth steel produced in the country the larger part is used in the form of castings, rather than in the manufacture of ingots for rolling.

Electric processes, which represent the latest development in the steel industry, are not an important factor yet, so far as tonnage is concerned, but they have already outstripped the production of crucible steel, and in fact in 1917 the production of electric steel was more than double that of crucible.

The total production in the United States of steel ingots and castings by all processes in 1917 exceeded 45,000,000 gross tons, which is almost exactly double the production of 10 years ago.

STEEL, HEAT TREATMENT OF. The physical structure of steel may and does vary to a marked degree according to the heat treatment that it has undergone; and that the strength, toughness and general usefulness of a structural member of steel may be largely controlled by the way in which it is subjected to the action of heat. Formerly it was assumed that phosphorus gives brittleness, that sulphur makes the metal red-short, and that the other properties are almost entirely dependent upon the percentage of carbon present. With the introduction of the microscope and modern methods of metallography in the study of steel and other alloys, it has been found that the structure and the properties of the material may be largely modified without any change whatever in the chemical composition, and as a consequence some very practical lessons have been learned. When steel of a coarse structure, but not necessarily brittle, is heated to a certain temperature and is then allowed to cool in air, or is quenched in oil or in water, the original structure is destroyed and is replaced by one of a very fine-grained character. Pure iron, when so coarsely crystalline as to resemble cast zinc, may be restored to excellent qualities by simply heating it to a certain temperature (known as the "critical point"); its subsequent structure resembling that which it possessed when it originally left the rolls. The old idea of the process of annealing was to reheat the material to a high temperature, and then to hold it for a time at that temperature, and subsequently to cause it to cool very slowly; but later researches showed that the temperature of reheating must not exceed 1,650° F., and that the time of cooling has little or no influence upon the result. It is altogether unnecessary to reheat and reforge the specimen, and, in fact, the material is apt to be still further injured by such a process. Since almost any piece of structural steel is liable to be rendered more or less crystalline during the operations through which it is necessarily passed, it is most desirable that the process of restoration be made a regular portion of the routine of manufacture. To permit this it is only necessary that proper furnaces be designed to admit the large pieces, and to permit a uniform temperature to be maintained in all parts, reliable pyrometers being of course provided so that the correct temperature may be maintained. The operation may then be performed upon every piece as the final stage in its manufacture. The result is elimination of danger of accident from weakness by crystallization. The microscope indicates that heating at high temperatures causes a great development in the size of the crystalline grains, and

that reheating to about 1,600° F. restores the original structure, or yields an even better one. A structural steel, although good in its normal rolled or forged condition, may easily deteriorate by being heated to a temperature a little above that to which steel is most commonly heated, previously to being rolled or forged. Steel that is made brittle by such heating, or dangerously brittle by exposure to considerably higher temperatures, can be completely restored to the best possible condition without remelting and without forging down to a smaller size. Practically all of the experimental results show, not only that the original good qualities of normally rolled steel can be restored after the material has been made brittle by the exceedingly simple expedient of heating to about 1,600° F. for a very short time, but also that the steel may even be made better than it was originally.

It was long ago noted that the influence of thermal treatment increases rapidly with the carbon content of steel. In one of Howe's experiments with a muffle the following variations were shown:

STEEL OF	Tensile strength per sq. in.	Elastic limit lbs. per sq. in.
0.035 carbon.....	750° C. 28,353	19,948
	1,100° C. 28,657	18,130
	1,300° C. 28,529	12,142
	1,400° C. 30,064	11,483
0.70 carbon and .68 Mn	750° C. 82,660	40,062
	1,100° C. 92,342	59,363
	1,300° C. 48,921	29,447
	1,400° C. 41,327	33,082
0.92 carbon and .240 Mn	750° C. 81,087	34,710
	1,100° C. 109,586	39,226
	1,300° C. 106,913	33,992
	1,400° C. 64,189	42,008

A yet higher carbon with less manganese yielded less tensile strength than the "0.92 carbon and .240 Mn," but a higher elastic limit. It will be noted that generally the best result was obtained by cooling from 1,100° C. These experiments were made in a closed muffle, with both slow heating and slow cooling. The elastic limit reaches a minimum at about 720° C., then rises rapidly on heating to temperatures of 750° to 850°, and then decreases steadily. The slower the cooling the lower elastic limit is to be expected. In the matter of elongation it has been found that with 0.50 per cent of carbon, as the initial temperature (for slow cooling) is raised, the elongation decreases moderately up to 1,200° or 1,300°. With higher initial temperature the elongation decreases rapidly. In the matter of tensile strength it is noted that the increase is more marked when cooling is done in the open air than in the muffle. With rapid cooling hardness and brittleness increase, without much reference to the initial temperature of cooling, so that the steel maker always has to consider his product from several different angles. If the steel is low in carbon it will be little affected by heat treatment, but if high in carbon the heat treatment is all important.

STEEL, MANUFACTURE OF CRUCIBLE. Crucible steel is so called because the ingredients from which it is made are melted in crucibles or pots. The name to-day is almost synonymous with "tool steel"—

meaning a steel containing at least one-half per cent of carbon, which will, therefore harden materially when plunged at a bright red heat into water or oil. Steel of lower carbon than this may be made in crucibles for especial purposes when hardness is not the chief quality desired. For example, steel castings are frequently made of crucible steel. The quantity actually so used in this country is only a few thousand tons per annum.

The practice of hardening steel is of great antiquity and is referred to by the early Roman and Greek writers. The ancient Egyptians heated iron, in some cases possibly of meteoric origin, in the forge until, by long contact with the fuel, it absorbed enough carbon to impart considerable surface hardening when quenched. The difference between oil and water hardening is referred to by Lucretius who says: "The finest tools are tempered in oil, which gives a more durable hardness than that imparted by water."

The fact that iron heated in contact with carbon absorbs some of that element, which renders it harder, seems to have been known for many centuries and prior to Huntsman's invention, in 1740, all steel for tools was made by the process of cementation. Especially in Austria and England the art and industry of converting pure wrought iron into cement- or blister-bar flourished, by which, as French says: "A steel was obtained which had uncertain percentages of carbon, higher on the outside than on the inside, and varying in hardness from one end to the other, according as the bar came in contact in the converting furnace, with more or less of the carburizing material, or a higher or lower degree of heat." It was to overcome this lack of uniformity that so-called "single" and "double-shear" were made, but Huntsman conceived the idea of melting the cemented-bar in crucibles, thus rendering it absolutely homogeneous and of uniform carbon contents throughout the mass. As first carried out, the melted steel was allowed to cool in the crucible, which was then broken away and the resulting mass was used as an ingot. About a century ago Mushet patented the production of steel made in the crucible by melting together soft bar iron and a certain amount of carbonaceous matter. This process did not amount to much until 1839, when Heath patented the use of manganese as an essential addition to crucible steel. In America the Mushet-Heath process of melting together in crucibles soft bar-iron, with or without a certain percentage of steel scrap, charcoal and oxide of manganese, spiegeleisen or ferro-manganese is more generally employed than the original Huntsman process of melting cemented or blister-bar. It has been said of Huntsman's invention that,—"The invention of cast-steel was second in importance to no previous event in the world's history, unless it may have been the invention of printing." Huntsman's process was rapidly adopted and at the time of his death there were several firms melting steel, and possibly 500 individuals and firms making files, edge-tools, etc., in Sheffield,—famous for its "thwytles" since Chaucer's day. Among these names appeared Spencer, Jessop, Sanderson, Parkin, Turner, Hobson and Rogers and these same names appear to-day in con-

nection with both English and American crucible steel works.

The Materials.—The base used for crucible steel is usually wrought iron. England, Germany and America draw on Sweden for the more expensive grades, and by many it is believed that Swedish materials possess some mysterious virtues not afforded by other irons, regardless of what the results of chemical analysis show. The Swedish irons are all made from charcoal pig iron and are refined by the Lancashire or Walloon processes. Some have claimed that these irons contain traces of vanadium and that to this they owe their virtue. They usually contain small amounts of manganese, while ordinary puddled irons are nearly free from this element. To the writer this seems more important than a possible trace of vanadium. A careful investigation of products made from Swedish and American irons of the same analysis has revealed absolutely no difference in the quality of the product, chemically, physically or by practical test in tools of divers sorts. Certain it is that rarely does Sheffield tool steel show as great purity as regards sulphur and phosphorus as is seen in the product of American mills. In America, while Swedish iron is still used to some extent, it has been replaced by selected open hearth bar and by the purer product of the puddling furnace. This commonly carries less than one-hundredth of 1 per cent of sulphur and phosphorus, and also contains much less copper than the Swedish irons.

In German and English tool-steels a combined percentage not exceeding 0.06 per cent of sulphur, phosphorus and copper is considered first class, while in America this combined percentage is about one-half as much and would not be expected to exceed 0.04 per cent in the best product.

Swedish bar or puddled bar may be and is melted directly or it may be first carburized by the cementation process. Cemented bar is used more largely abroad than in America. For the purpose of adding carbon, when the cemented bar is not used, it is customary to use either a pure Swedish charcoal pig iron or the American product known as "washed-metal." Both carry about 4 per cent carbon and are low in sulphur and phosphorus, but the former carries rather variable quantities of silicon and manganese, from which washed metal is nearly free. This is an advantage in favor of the Swedish pig, if the silicon and manganese can be maintained fairly uniform and not excessive in amount. In some cases all the carburizing in the crucible charge is effected by means of charcoal. Small quantities of oxide of manganese or ferro-manganese are usually employed, and for special steels metallic nickel, manganese, tungsten, chromium, or molybdenum or their ferro-alloys are employed.

Crucibles.—In England, clay crucibles are almost exclusively used. They are nearly always made in connection with the works using them, the mixing usually being done by men who tread the clay with their bare feet. Little or no machinery is used in their production. The mixed ingredients are made into balls of suitable weight and these are dropped into a mold and a plug shaped like the inside of a crucible is driven in, forcing the clay up into

the mold and around the plug, which is then withdrawn and the crucible removed from the mold and dried for several weeks. Before using, it is "annealed" or baked and is always filled while hot. The crucibles last only about three heats, carrying 60 pounds at the first heat and a less amount on each subsequent charge. This is because the metal attacks and weakens the crucible at the slag line and hence the level of the metal is lowered in the pot on each succeeding heat.

Graphite crucibles are generally used in Germany, Austria and the United States. These according to analysis, quoted by Howe, may contain from 20 to 83 per cent of graphite, about 50 per cent being commonly used in America. The best Ceylon graphite should be used. Artificial graphite made in electrical furnaces is unsuitable for crucibles because of its granular rather than lamellar structure. With the graphite is used either clay or a mixture of clay and old crucibles finely ground. It is also customary to use a little coke dust in making clay crucibles. Graphite crucibles are much larger than clay ones and will carry the customary 90 to 100-pound charge from 5 to 10 heats. They will stand much abuse, especially in the way of sudden changes of temperature, and need not be filled hot each time. Indeed, it is quite customary to allow them to cool off completely between heats, when they are cleaned and inspected. Graphite crucibles cost from five to eight times as much as clay crucibles, but this disadvantage is more than offset by their greater endurance and the much greater production per crucible. The disadvantage frequently mentioned, that they impart variable amounts of carbon and silicon to the steel, is more fancied than real.

Furnaces and Fuel.—Several types of furnaces have been employed for crucible steel melting, but such steel for tool purposes is nearly always melted in shaft furnaces using coke as fuel or in Siemens regenerative furnaces using gaseous fuel,—either producer or natural gas. The latter is almost exclusively used in the Pittsburgh district and seems to be the ideal fuel because of its uniformity of composition and its freedom from sulphur. In addition to these fuels, anthracite has been employed to a limited extent in a special form of shaft furnace, somewhat resembling the coke-holes or furnaces. They differ in this, however, that they require forced draft and to provide this the ash-pit is enclosed and air is driven into it and thence through the bed of anthracite on the grate by means of a fan blower. Waste heat from anthracite furnaces may be used for heating steam boilers. Petroleum has been used for fuel in the Nobel furnace for melting crucible steel for castings, as in the Mitis process. We now hear little of anthracite or petroleum for crucible steel melting, and the writer is not aware that either of these fuels is actually being used in America at the present time.

The Sheffield coke-holes or shaft-melting furnaces hold only two crucibles each, and they are not run at night. The furnace itself consists of an oval chamber about three feet deep to the grate bars and a foot and a half to two feet in section. These holes are arranged around one or more sides of the melting-house.

Their cover-bricks are just above the floor level. The melting holes are connected either to separate flues, some half dozen of them being united to form one large chimney, or else the individual flues may be united in a large common flue and stack. The draft is roughly regulated by inserting bricks in the flues. Beneath the furnaces there is always a large ash pit and cellar. In Sheffield the crucibles, after air-drying and annealing, are put into the furnace and well packed around with coke, and the materials to be melted are charged into the red hot crucible through a sheet iron funnel. The crucible rests on a stand and this in turn is supported on the grate bars. The charging being ended, a cover is placed on the crucible, the fire is urged and during the operation the coke must be replenished at least twice. Three heats from a crucible constitute a day's work and require about 12 hours' time, and three heats, also, is about the life of the crucible.

The regenerative gas furnace, which is used exclusively in the United States, has never been popular in England, although it is much more economical as regards fuel consumption. Numerous reasons have been given to explain why it is not used in Sheffield. Strangely enough it has been stated that gas fires are not under such good control as coke fires, or again, that the entire crucible and its contents are not heated to a uniform temperature. Whatever weight these objections may have, it is interesting to note that whenever English capital has been invested in the crucible steel business in America, graphite crucibles and gas-fired regenerative furnaces have been adopted without apparent hesitation.

The American furnace consists of from 2 to 10 melting holes in a row, and each hole will accommodate six crucibles at a time. Each hole is provided with three ports on either side through which the gas and air and the products of their combustion pass. The direction of flow of the gas and air is reversed about every 15 minutes, in the way common to all Siemens regenerative furnaces. Beneath and at either side of the melting holes are the regenerative chambers, one for gas and one for air on each side. The chambers are filled with so-called checker work of brick, which takes up heat from the outcoming gases or imparts it to the entering gas and air. The furnace of Dawson, Robinson and Pope, which is said to be giving very good results at Jessop and Sons, Sheffield, differs from the American furnace in that all four regenerative chambers are on the same side of the melting holes, which have four ports each. The melting hole is curved or horse-shoe shaped on the side opposite the ports. The gas and air thus enter by two of the ports and rush around the curved outer edge of the furnace and down the other two ports. The six crucibles break and impede the passage of the flame and absorb its heat as it passes.

The melting holes have a layer of coke from six to eight inches deep in the bottom and on this rest the crucibles. The crucibles are usually filled carefully by hand, while cold, and are set into the furnace. The crucibles are well adapted to stand this sudden change of temperature if they have been well baked and have been kept in a dry place prior to use. Unlike the coke furnace, the gas furnace is run continuously, day and night, from Monday morning

to Saturday afternoon, from 33 to 36 heats constituting a week's work. These furnaces will last from eight months to a year or even longer before the holes need relining or the checker work needs replacing. Coke furnaces require relining about once a month. The first cost of a gas furnace is much greater than that of the coke furnace, but the crucibles are more readily accessible in them and they are much more economical of fuel. A ton of ordinary bituminous coal, burned in a producer, will melt a ton of steel, while the coke shaft furnace requires about three tons of the more expensive coke to melt a ton of steel. Commenting on this phase of the subject, Harbord, the distinguished English authority, says: "The economy in fuel, ease with which gas can be regulated, freedom from clinkers on pots, offer so many advantages over the coke-hole, that notwithstanding past failures of gas furnaces, there seems every prospect of this or some similar gas-fired furnace being very largely adopted in crucible steel melting." By the "past failure of gas furnaces" Professor Harbord must refer to their failure of general adoption in England rather than in any real difficulty with the gas furnace itself as compared with coke-holes or other furnaces. More crucible steel is melted in gas furnaces than in all other forms combined.

Melting.—The materials being charged into crucible the fire is urged in the case of coke or more gas is turned on in the case of Siemens furnaces, until at the end of about two or three hours the materials are melted. In the case of mixtures consisting of much high carbon scrap, pig iron or cemented bar the melting takes place more quickly than with mixtures consisting largely of puddled iron and charcoal. When the melter thinks the contents are about melted, the cover of the crucible is raised and the contents examined by the melter who prods about in the crucible with a long iron rod to detect unmelted pieces. The melting of large pieces of steel scrap takes place in a rather unexpected fashion,—the inside seems to melt first and to run out, leaving a shell looking exactly like the original piece, floating around on top of the metal.

After the materials are "clear melted," the heating is continued for an extra half hour or more and this is known as the "killing" heat. If the metal were poured into the ingot molds immediately after melting, unsound and spongy ingots would result. During the killing some silicon is taken up from the walls of the crucible by the metal and this seems to assist in making sound castings. Then, also, the oxide of iron which is present in the metal has a chance to react with the carbon in the steel or in the walls of the pot and is thus reduced to metallic iron, while oxides of carbon are formed and eliminated. Steel that has been given sufficient killing, if cast in open molds and allowed to cool spontaneously, would be quite free from blow holes, but would be deeply piped. In actual practice means are employed to eliminate the pipe, and the ingots are perfectly sound from top to bottom. The tendency to eliminate gas during solidification is offset in varying degree by silicon, manganese and aluminum.

The Ingots.—The crucibles, after the killing heat, are withdrawn from the furnaces and

the small quantity of flux or slag always present is "mopped" off. The metal is then poured or "teemed" into molds. The molds are of cast iron and usually in two parts, held together by rings and wedges. Before use, the molds are smoked with resin. When it is desired to make large ingots, the product of any number of crucibles is cast into one mold. Until quite recent years large castings for ordnance, armor and projectiles were made of crucible steel. The Krupp works continued this practice longer than the leading English and American works. Crucible steel ingots weighing 30 tons and above and requiring over 1,000 crucibles of metal have been made. It is now 25 years since the general use of crucible steel for heavy ordnance, shafting, cranks, etc., ceased, though some is still used for these requirements.

Grading the Ingots.—The quality of steel depends upon the method of manufacture, the analysis and the method of handling. Even when of almost identical analysis, crucible steel takes first rank for quality with electric steel a very close second, open-hearth steel stands third and to Bessemer must be assigned last place. The exact reason why this is so is not known definitely, but the fact is generally admitted. The quality of crucible steel depends upon the nature of the raw materials entering into the crucible mixture. In general, the lower the percentages of sulphur and phosphorus the better the steel, and the higher the carbon the more pernicious is the effect of these unwelcome metalloids. The degree of carburization is generally referred to as the "temper" of an ingot. In a works making hundreds or even thousands of small ingots per day it would manifestly be impossible to analyze each ingot for carbon. Fortunately, this is not necessary. Very small differences in carbon so change the fracture or crystallization of the ingot that the skilled inspector can detect by the eye differences of carbon not greater than one-twentieth of 1 per cent, within the limits of carbon most used for tool steel, say, 0.90 per cent to 1.40 per cent carbon. The presence of large amounts of tungsten, chromium, molybdenum and other alloying metals interferes with or precludes entirely the estimation of carbon by the eye. Other elements being within the usual limits, e.g., silicon and manganese from 0.10 per cent to 0.25 per cent and sulphur and phosphorus from 0.01 to 0.025 per cent the percentage of carbon is the most important factor in determining the suitability of any steel for a given purpose. According to Thallner, steel containing upward of 1.5 per cent carbon may be called very hard and is suitable for turning and planing knives, drills, razors, etc. Hard steel of 1.25 per cent carbon is suited for ordinary turning and planing knives for use on materials of medium hardness, also for rock drills, scrapers, cutters, etc. Medium hard steel of 1.0 per cent carbon is suitable for screw taps, coining dies, chisels, punches, etc. Thallner calls steel of 0.85 per cent carbon tenaciously hard, and recommends it for screw-taps, cutters, broaches, matrices, swages, pins, bearings, chisels, gouges, etc. Steel of 0.75 per cent carbon is tough and suited to tools requiring rough handling, hammers, shear blades, drifts, springs, cupping tools

and certain kinds of needles. Soft tool steel is rather a misnomer, but the term is used in a relative sense, and applied to steel of about 0.65 per cent carbon, for blacksmith's tools, bolts and for welding to harder steel to stiffen and toughen it. No arbitrary list of this kind can fit all cases. In general, the crucible steel business is one involving a tremendous amount of detail, care and watchfulness. The temperature of the metal must be carefully guarded and controlled at every step—melting, welding, cogging, rolling or hammering, and when the steel reaches the customer equal care is required to forge, to harden and to temper the finished tool. The proper selection and blending of raw materials or the choice of the proper quality and carbon for a given use, and its successful fabrication may not be learned from books or acquired in a day, but are a legitimate part of the stock in trade of Böhler, in Styria; Jessop or Huntsman, in England; Sanderson or Halcomb, in America, and other firms with established reputations.

STEEL, OPEN HEARTH MANUFACTURE. The process of producing steel of this class derives its name from the type of furnace used—an open hearth. In European practice the process is known as the Siemens-Martin, receiving its name because of being originated, developed and perfected by two eminent and early metallurgists (1864-67). The process is conducted either in an acid or basic furnace depending upon the character of the raw material treated.

There are several divisions of the process. The original plan was to treat a charge of all pig-iron with the assistance of iron ore to convert into steel. Later a modification was introduced wherein pig-iron and steel or wrought-iron scrap were melted together and subsequently refined to steel. The first named constituted the Siemens process and the second the Siemens-Martin. To-day the essentials of both processes remain, but modifications have been introduced from time to time. The Monell process, conducted in an open hearth furnace with a basic lining, consists of a charge of molten pig-iron to which certain quantities of iron ore and lime are added which fuse to form a slag and which slag flows out of the furnace at a point above the surface of the molten metal, thus carrying with it certain impurities in the charge of metal it is desired to remove. The ore and lime are added at certain intervals to make the overflow of slag continuous until the desired stage of purification is reached.

Next in importance is the Talbot process, also conducted in a basic lined open hearth steel

furnace. The furnace for this process is of movable type and is so constructed that the body can be tilted forward to discharge the bath of metal through an opening placed at the level of the bath, or it can be moved in the opposite direction to pour out of suitable openings placed at a higher point greater or less quantities of the slag. The process is a continuous one. A full charge of metal—about 200 tons—which may consist of molten pig-iron direct from the blast furnace, or a mixture of pig-iron and steel scrap is treated by additions of iron ore and lime until proper pre-determined conditions are reached by slag action. At that stage the bulk of the slag is poured off and about one-third of the refined charge is withdrawn into a ladle allowing the balance to remain in the furnace. The steel in the ladle is recarburized and teemed into the ingot molds and an additional charge of impure molten pig-iron is poured into the furnace in sufficient quantity to bring the contents up to the initial charge. The remaining slag is then removed by tilting the furnace, a fresh slag made by ore and lime and the refining operation repeated. In the second treatment, however, the interval of time is considerably reduced because the residue of refined metal from the initial charge greatly dilutes the succeeding addition of molten impure stock and so making a smaller total of objectionable elements to remove by slag action. Under normal conditions the furnace is never empty excepting at week ends when incidental repairs are made. In Siemens-Martin open-hearth practice the furnace is emptied completely at the end of each heat. It is then patched up, as may be necessary and recharged.

Another process of recognized importance is the Bertrand-Thiel process. It is used in Europe to some extent. Two open-hearth furnaces are used, one acid lined and another basic. One furnace may be placed at a higher level than the other so that the charge treated in the upper furnace can be tapped directly by gravity into the one below. Or the furnaces may be placed at the same level and the charge transference from one to the other be accom-

plished by the basic process, by which the metal is treated and fully refined in the second stage of the process. It is a combined acid and basic process whereby pig-iron is converted to steel and allows the use of stock so high in phosphorus and sulphur that it could not be successfully refined by either process singly. In the acid-lined furnace the charge of molten metal is desiliconized and partly decarburized, but not desulphurized or dephos-

plished by ladles. In the Hoersch modification of this process only one furnace is employed, the metal being temporarily transferred to a ladle while the basic lining is being spread, when it is returned for final treatment. The principle of the process is that a charge of impure stock is first treated in an acid-lined furnace to greatly lessen by nearly full removal certain elements objectionable to further

phorized, but when transferred after such treatment to a basic-lined furnace, either by gravity or ladle, the decarbonization, desulphurization and dephosphorization are completed to meet any requirements. In the United States and Canada the Bertrand-Thiel process has, to some extent, been modified by the introduction of the Duplex process, in which an acid Bessemer converter replaces the acid open-hearth furnace, the Bessemerizing effecting the same action practically in regard to silicon and carbon removal from the charge which is subsequently transferred to a basic open-hearth furnace for removal of the phosphorus and sulphur and further purification.

Construction of Furnaces.—The furnace is built on the regenerative principle. The waste heat of the spent gases from fuel consumption being absorbed and stored in the walls

STEEL

Tapping open hearth

and partitions of chambers placed below the furnace body and at each end of it, can be utilized for preheating the air necessary to promote complete combustion of the fuel. Without such preheating it is not possible to depend upon flame temperature alone for melting and preserving the desired fluidity of the charge.

Reference to Figs. 1 and 2 will outline the general form of a stationary open-hearth furnace. The furnace body or melting chamber is lined with high-grade refractory bricks. The whole is braced and supported by girders, tie rods and plates. In an open-hearth furnace for the production of acid steel, the roof, hearth sides and end walls are constructed of silica bricks. The roof is very thin and of the purest silica bricks set with a little lime. It is arched and suspended from above so as not to weigh upon the side walls. The regeneration chambers are lined with fire bricks. The bottom of the hearth is lined with 18 to 24 inches in depth of fire brick over which is spread about half an inch of silica sand, the surface being dished or so formed that the metal when leav-

ing the furnace through the tapping hole will flow and drain toward it. When a new furnace is ready to receive a charge the gradual preliminary heating up is of sufficient degree to harden the sand by slight fusion or sintering so that the hearth will preserve its shape and not be broken down by rough usage or attrition when receiving a charge of stock. In a furnace for the manufacture of basic steel, the roof walls, sides and end walls above the slag line are formed of silica bricks, but the hearth is lined in the pan with first quality fire-brick followed by bricks composed of magnesite, and at the junction of the silica bricks and the magnesite a neutral parting of chrome ore is placed to prevent fusion of the two kinds of bricks at furnace-working temperatures. The upper courses of magnesite bricks will stand about 6" to 8" above the slag line. In other particulars of brick-work the construction is the same in both classes of furnaces.

The various dimensions, areas and volumes of body, down-takes and regenerator chambers vary mainly with the capacity of the furnace in regard to tons per heat or operation. The

width of the furnace is usually between 12 and 15 feet and does not exceed 16 feet. The length and depth of hearth are not fixed, but the area of both closely follows certain val-

FIG. 3.—ARRANGEMENT OF FURNACE PORT FOR BURNING NATURAL GAS.

ues per ton. The length and depth of regenerator chambers will vary also, but the volumes as a rule closely follow standard figures per ton. Generally stated the following cover the various dimensions, etc.:

Hearth area, 9 sq. ft. per ton.
Chamber volume, 90 cu. ft. ($\frac{1}{2}$ for gas, $\frac{1}{2}$ for air, per ton.)
Air port area, 16 sq. ft.
Gas port area, 7 $\frac{1}{2}$ sq. ft.
Stack, diameter 4-5 ft., 100'-160' height.
Producer area, 3 $\frac{1}{2}$ sq. ft. per ton.

Fuel.
Coal, 700 to 1,000 lbs. per ton.
Natural gas, 800 to 1,000 cu. ft. per ton.
Oil, 60 to 100 gals. per ton.

The following figures represent hearth measurements for representative capacities:

Capacity	Length x Width	Hearth Area
30 tons	27 x 10 ft.	270 sq. ft.
50 tons	34 x 13 ft.	438 sq. ft.
200 tons	40 x 16 ft.	640 sq. ft.

The last item covers the dimensions of a Talbot furnace which has a deeper bath than other furnaces. The depth of bath varies from 12 inches for a very small furnace (5 to 15 tons) to 24 inches for a 50-ton furnace. The Talbot bath is over 36 inches deep.

Fuel and Accessories.—The choice of fuel varies with the location of plants. In and around Pittsburgh natural gas is extensively

used and is really the ideal fuel. It is not passed through the regenerator chambers but is fed directly into the furnace port (Fig. 3). It is uniform in composition, possesses the highest calorific value and does not contaminate the bath. Next in heating value is crude petroleum or residuum, a by-product in the distillation of petroleum. Both have advantages in uniformity of composition and ease of control. Oil is pumped, under pressure, from storage tanks delivered to a suitable oil-burning device where it is atomized by compressed air or steam before ignition in the furnace (Figs. 4 and 5). The next preferable source of fuel is the gas producer (Fig. 6). In this apparatus bituminous coal is gasified and the gaseous matter conveyed through mains controlled by regulating valves (Fig. 7) before entering the regenerator chambers. The principle of operation is to force through a mass of incandescent carbon air and steam. On top of the glowing coals fresh fuel is regularly fed to keep the bed at a constant level. The bed must be frequently poked to

FIG. 4. — OIL BURNER FOR OPEN HEARTH FURNACES.

prevent holes forming, allowing air and steam to pass through un-decomposed. The bottom of the producer rests in a tank of water to prevent too much air from entering, since the air necessary to form a good working gas must be under control by compelling it to pass through the blower. The gas is apt to vary in composition and is not always constant in volume. A ton of coal treated in a producer will give about 160,000 cubic feet of gas. The average composition is as follows:

Carbon Monoxide.....	27 per cent by volume
Carbon Di-Oxide.....	5 per cent by volume
Hydrogen.....	10 per cent by volume
Nitrogen, etc., by diff.....	58 per cent by volume

CALORIFIC VALUE OF FUELS.

	Per cu. ft.
Natural Gas.....	900 to 1000 B. T. U.
Oil.....	16-1700 B. T. U. lb. or 913.760 B. T. U.
Producer Gas.....	130 to 140 B. T. U.

Furnace Operation—Acid Practice.—In order to produce steel by any open-hearth process it is necessary that a certain amount of carbon be introduced with the metal to be converted. For that reason ordinary pig-iron which will contain 2.5 to 3.5 per cent of total carbon is required. The presence of carbon lowers the fusing point of iron and when charged in an open-hearth furnace it is comparatively easy to liquify the bath at an early stage of the

process and maintain it to the end of the operation. Low-carbon stock, such as steel or wrought-iron scrap, cannot be used singly because if exposed to flame action it would not fuse, but would be pasty and viscous, causing loss. The charge may be all pig-iron or a mixture of 20 per cent pig-iron and 80 per cent

FIG. 5. — CONSTRUCTION FOR OIL BURNING OPEN HEARTH FURNACE. (Half Section at Centre).—(1) Opening for oil burner; (2) air port from regenerator chamber; (3) air port from regenerator chamber.

scrap. The usual American practice is 50 per cent of each.

The acid process is so-called from the character of the hearth lining which is formed of nearly pure silica sand, a substance, chemically an "acid." It is fairly refractory but must carry a small percentage of foreign elements to very slightly lower its fusing point. In forming the hearth, as has been mentioned, it must be hard to resist wear and at the same time be inert under strong actions within the bath of molten metal at high temperature. It has no affinity for sulphur and phosphorus, but will fuse with oxides of iron or manganese. For the latter reason care is taken with heat manipulation to prevent scorification of hearth by such oxides. Since specifications for finished material, such as boiler plates, structural material, etc., state that the sulphur and phosphorus be kept below certain limits, the choice of raw material in regard to those elements is also subject to limits, and because of non-removal, in refining, whatever sulphur and phosphorus may be present in the initial charge will appear in the finished product in like proportions.

Raw material for acid treatment is called "Acid Stock," and the following will represent average analysis:

Scrap Steel.—Sulphur, 0.04% or less; phosphorus, 0.04% or less.

Pig Iron.—Carbon, 2-3.5%; silicon, 0.50-1.5%; sulphur, 0.04% or less; phosphorus, 0.04% or less; manganese, 0.50-75%.

The figures on carbon, silicon and manganese for scrap are not specified, because the scrap is always the result of some previous converting process and is, therefore, low in those elements. The shapes may be ingots, blooms, steel castings, tires, springs and rolling-mill waste. If scrap composes part of the charge it will be put in the furnace first followed by either molten pig-iron brought in a ladle direct from the blast furnace or iron in the forms of pigs. Before the iron addition some little

time is allowed for the scrap to heat or partly melt. The chemical action is mainly a decarbonizing one or rather an oxidizing one. The first elements to oxidize are silicon and manganese of the charge forming respectively silica (SiO_2) and manganese oxide (MnO) which fuse readily and unite to form part of the slag. The slag is mainly composed of SiO_2 and FeO . The FeO (ferrous oxide) being formed mainly in the melting of the scrap and the silica from sand carried in mechanically with the pig-iron and the oxidation of the silicon in the metals charged. The following analysis represents a normal acid open-hearth slag:

SiO_2	52.00 per cent.
MnO_2	17.50 per cent.
FeO	28.50 per cent.

Under flame action the temperature of the bath is gradually increased mainly because the heat stored in the regenerator chambers and radiated to the air passing through them to support flame or fuel combustion increases the efficiency. The checkers nearly fill both sets of chambers and are formed of first quality fire bricks so placed that numerous passages three

FIG. 6. — GAS PRODUCER.—(1) Coal hopper; (2) poke holes; (3) steam pipe; (4) blower; (5) connection with gas main; (6) water seated ash pan; (7) grate.

to three and one-half inches square are formed both vertically and horizontally, thus offering very large areas for the waste gases to pass through and give up their heat to the numerous bricks. The temperature at which the furnace is operated ranges from 1600° to 1700° C. (2912° to 3092° F.). The waste gases leaving the furnace body are about 1100° to 1650° C. and after passing through the chambers should normally measure about 500° to 600° C. at the stack. At regular periods the course of the flame and gases are reversed so that while one set of chambers are giving up heat to the inflowing air or gas (producer only) the other is absorbing the heat from waste products of combustion. Without a careful regulation of fuel there would be danger of melting the brickwork in the furnace because with each reversal there is a constant increment of temperature carried into the furnace melting chamber.

The bath under increased temperature becomes very liquid both in regard to the metal and slag. There is a lively action caused by the burning of the carbon and silicon which draws upon the oxygen in the slag and oxides dissolved in the metal. To hasten the removal of carbon, iron ore is added from time to time which produces the following reaction:

The reduced metallic iron entering the bath, adding to the yield of metal while the gaseous carbon bubbling through the bath keeps it moving and so promotes homogeneity, an advantage in favor of any open-hearth process. When the carbon removal has been completed or has proceeded to any desired point, as indicated by the fractured appearance of test pieces taken at intervals, the metal is tapped out of the furnace by breaking open with an iron bar the tapping hole previously closed, before charging with some suitable refractory material. While the metal is flowing into a preheated

clay-lined ladle measured quantities of either spiegeleisen or ferro-manganese are added which have a cleansing effect upon the steel and performs the function of recarburizing it. They are alloys of iron and manganese each carrying respectively 20 per cent and 80 per cent of manganese with about 5.5 to 6.0 per cent of carbon. It is possible to stop the refining process at any stage, and by using varying quantities of the substances just named known as deoxidizers or recarburizers, there is offered a possibility of producing numerous grades of steel. Without any additions of manganese at the end of an open-hearth operation the metal would be charged with oxides which would interfere with its rolling properties. The action of manganese is to liberate such oxides by making them readily fusible, when they float upward and mingle with the slag above the metal. Metal not well deoxidized is likely to

crumble or crack when forged, rolled, hammered or welded.

After the steel is tapped into the ladle and from that into ingot molds (Fig. 8) they are stripped therefrom when the metal has solidified and the ingots are reheated and rolled out into various shapes.

FIG. 8.—GENERAL ARRANGEMENT OF MOLDS WHEN CASTING INGOTS WITH BOTTOM POURING LADLE.

Basic Practice.—To successfully conduct the basic open-hearth process it is necessary to have a hearth lined with such material that will withstand the action of slags highly charged with lime. The presence of lime in moderate or excessive quantities in an acid furnace would be fatal to the hearth because of the strong fluxing action between silica and lime when brought together at high temperature. A basic lining in general practice consists of calcined magnesite, a substance carrying a high percentage of magnesia. In furnace construction it is ground and mixed with about 10 per cent of anhydrous tar, then rammed in and shaped to the sloping form. At the beginning of the heating of the furnace the tar is carbonized into a solid cinder. It can also be mixed with pulverized basic slag which assists the sintering and hardening effect. A hearth of magnesite so formed is practically inert under the action of a limey slag, but will fuse or cut if siliceous matter should be present excessively. The life of a magnesite hearth is practically indefinite. With a hearth of basic and refractory material, such as magnesite, there is offered an opportunity to treat a charge of such stock carrying a high content of elements not removed in an acid hearth; namely, pig-iron with 1.00 per cent of phosphorus and 0.07 per cent of sulphur is easily treated, so that 95 per cent of the phosphorus and 75 per cent of the initial sulphur can be removed by the action of the slag, consisting largely of lime and iron oxide. The only element that is objectionable is silicon and basic stock or raw material is selected with amounts of silicon not exceeding 1 per cent. To get a slag of the necessary dephosphorizing and desulphurizing activity 10 to 15 per cent of the charge is made up of limestone of a pure variety with ore added from time to time. Silicon under the oxidizing action of flame and additions of iron ore to the bath of liquid metal, will be converted to silica and combine with the lime of the slag and if excessive rob it of its power to absorb phosphorus and sulphur. The details of charging are the same as in acid melting excepting that a charge is best

made up of 50 per cent of pig and 50 per cent of scrap, when scrap is used, or the charge may be all direct molten metal. It is desirable to use scrap moderately because it is easier to promote liquation with a higher carbon content initially.

The layer of supernatant slag is thick in a basic heat and more heat units are required to penetrate it than an acid slag. For that reason the fuel consumption per ton is greater in the basic process.

The flame manipulation is the same as in acid melting as is also the carbon oxidation by the action of iron ore. The details of re-carburizing are followed as in acid practice. During the progress of the heat samples are frequently taken which, in addition to being studied for the carbon content, are also tested to determine how far the dephosphorizing action has gone. The heat is not tapped until its removal is complete or only a few thousandths of 1 per cent remain. There is some tendency on the part of the phosphorus to revert to the metal after it has been tapped into the ladle. The amount given up by the slag at that stage varies directly with the quantity of phosphorus charged initially. But with proper slag conditions and care in stock selection the re-absorption of phosphorus is not excessive. Beginning with pig-iron carrying 1 per cent of phosphorus and an equal amount of scrap with not more than 0.1 per cent a heat of basic steel can be produced to equal in analysis acid finished material.

When the furnace is emptied after an operation some unavoidable cutting of the hearth at the slag line is patched with basic material of a cheap kind, usually dolomite, a double carbonate of lime and magnesia. There is not, under normal conditions, any cutting of the hearth below the slag line since the function of the hearth is only a refractory one playing no part in the purification of stock, that function being effected only by the calcareous.

While there is little difference in the physical qualities of acid and basic steels, engineers are accustomed to specify acid steel for most structural work.

In a 30-ton furnace it is possible to produce 18 heats per week of six working days. In a 50-ton furnace 12 heats per week is an average, either on acid or basic practice.

Steel Castings.—For marine, locomotive, freight and passenger car, electrical and general machinery construction it is important to have certain parts of great strength and elasticity. For such purposes steel-castings are preferred to gray-iron castings. In the United States the industry is increasing rapidly. The sources of supply are mainly divided between acid and basic open-hearth steel with moderate productions by small Bessemer, crucible and electric processes.

During the year 1914 the total production was as follows:

Acid open hearth castings.....	228,742 tons
Basic open hearth castings.....	301,206 tons
Bessemer (Tropenas) castings, etc.....	43,437 tons
Crucible castings, etc.....	8,920 tons
Electric castings.....	6,386 tons

Open-hearth castings generally enter into heavy parts weighing several hundredweights

to tons or more each, but do not enter into parts weighing a few pounds. For lighter parts the Bessemer and crucible processes fill a special field.

So far as equality and reliability of output is concerned in open-hearth castings there is no choice between acid and basic steel. In the early history of the processes (open hearth) the acid held sway, but with the development of the basic process it has largely met the growing demand for steel castings in spite of the fact that at first basic steel was more uncertain in its qualities.

For the production of open-hearth castings the details of construction and operation are essentially the same as for ingot practice. The main differences are that direct molten metal is not used, the charges being made up of cold, raw material (pig-iron and scrap). The sizes of furnaces vary from 10 to 25 tons per heat.

In the manufacture of steel castings problems are encountered which are unknown in ingot practice. It is comparatively simple to pour liquid steel into such receptacles as ingot molds but when pouring it into sand molds designed to cast shapes more or less intricate with various thicknesses of metal, greater or lesser length and irregularities of section than is found in the plain columnar lines of ingots the complexities become quite numerous. It is necessary that the steel be more fluid and hence hotter. This condition is secured by starting with a siliceous iron. The common difficulties encountered are lack of solidity, liability of the castings to crack or separate when cooling, particularly in complicated designs where there may be different rates of cooling in sections of unequal thickness. These difficulties are not insurmountable, but their avoidance calls for constant care and watchfulness and a high degree in skill in keeping conditions regular and uniform in the furnace melting practice and also in the molding and coring of designs.

For molding purposes a high-grade silica sand is preferred, one that is highly refractory and that will not fuse at the temperature of liquid steel—about 1600° C. An impure sand will stick to steel castings and make rough unsightly surfaces. The sand must be of such a formation that there will be voids between the grains to permit a free escape of the gases formed within the mold when the hot steel is poured into it. Silica sand is devoid of any bond, and, to allow it to retain the form of the pattern after the sand is rammed around it and the pattern withdrawn, a small amount of plastic fire clay is added to the sand with a little water, followed by thorough mixing to furnish the necessary bond or stability to the molding mass. Sometimes a mold is baked, or it may be used without any drying. The first is known as "dry sand" and the other a "green sand" practice.

When the mold is filled with the liquid steel

the molding mass under the high temperature disintegrates or loosens and should allow a free movement of the casting which contracts when cooling. Should there be a resistance to such a movement in cooling the casting will be liable to crack at points when the resistance and stresses are the greatest.

To promote solidity in steel castings it is the practice to add at the end of the refining and decarburizing operation certain amounts of ferro-silicon and ferro-manganese. The former may carry from 10 to 50 per cent of silicon and the latter usually about 80 per cent manganese. The combined action of the alloys is to thoroughly deoxidize the steel by uniting with the dissolved oxides, flux them so that they become separated from the liquid steel and enter the slag on top of the bath of metal and restore to the steel the desired percentage of carbon. Were the oxides not removed there would continue, so long as the metal remained liquid, a reaction between them and the small quantity of carbon always present in a bath of liquid steel, so that there would result a formation of gaseous carbon. Without a stoppage of that action the metal, if fractured when cool, would be found to be more or less honeycombed—an undesirable condition in any casting.

The value of a steel casting, physically considered, depends upon its elasticity, toughness and ability to resist heavy duty. The elasticity is controlled by the carbon content of the finished casting and that will vary with the requirements of its service. Steel castings are divided into three grades: Soft, medium and hard. Standard specifications give the following figures as the physical properties:

	Soft	Medium	Hard
Tensile strength lbs. per sq. in....	60,000	70,000	85,000
Yield point (elastic limit) lbs. per sq. in.....	27,000	31,500	38,250
Elongation per cent. in two in....	22	18	15
Contraction of area per cent.....	30	25	20

Approximately the following will represent the ranges of chemical composition for the foregoing:

	Soft	Medium	Hard
Carbon, per cent....	0.17 - 0.20	0.20 - 0.30	0.30 - 0.40
Silicon, per cent....	0.25 - 0.35	0.25 - 0.35	0.25 - 0.35
Sulphur, per cent....	0.015 - 0.05	0.015 - 0.05	0.015 - 0.05
Phosphorus, per cent.....	0.02 - 0.04	0.02 - 0.04	0.02 - 0.04
Manganese, per cent.....	0.50 - 0.75	0.50 - 0.75	0.75 - 1.00

In order to increase the ductility of castings, the ability to resist shock or impact without fracture, they are subjected to an annealing process, which treatment consists of a careful heating to a temperature that releases original cooling stresses and refines the grain of the metal. In a steel casting cooled from casting temperature there is a tendency of the crystals to become enlarged and with that condition the metal may be of a doubtful value, since a coarse internal structure is more or less brittle, but by heating to a temperature to or about a

	1914	1909	1904	1899

All others combined.....	21,593	14,426	1,221	4,223

full cherry red the coarse crystals become broken up and replaced by others of much finer mation. With that internal structure the ductility of the metal is greatly improved by removing all previous brittleness. The refining temperature varies with the carbon content of the steel to be treated. The higher the carbon the narrower the ranges of temperature for refining. The temperature need not be so closely observed when the percentage of carbon is low. It is a rule, however, that with the proper temperature being known, the heating below the refining range does not accomplish anything in changing the crystalline formations. Too high a heating will cause the crystals to increase in size. The length of time consumed in heating a steel casting to anneal, varies directly with the section, but after the piece has reached the proper temperature the fire can be drawn.

The location of the refining range can best be determined by a pyrometer and a microscope to study the various degrees of crystalline structure which reflect the rates of cooling from various temperatures.

With the carbon content given to control the tensile strength and elasticity (usually one-half of the tensile strength), the maximum degrees of toughness in any grade of steel casting can only be obtained by careful heat treatment or annealing.

The other elements, silicon, sulphur, phosphorus and manganese, each have characteristic properties influencing the ultimate qualities of the product. An excess of any one tends to interfere with the best results in service. Long practice, however, has established certain ranges of composition as being suited to both producer and consumer.

For the year 1914 the census of manufactures reported 140 establishments in the United States engaged in making open-hearth steel, and employing in this industry a total of 864 hearths or furnaces. Of the whole, 99 establishments operating 706 furnaces made basic steel and the remainder, with 158 furnaces, made acid steel. The daily capacity of all the basic hearths combined (double run) was 85,471 tons; that of the acid hearths, 8,179 tons.

The rapid and steady growth in favor of basic steel is well illustrated by the comparative figures furnished by the census, and tabulated on preceding page, the figures expressing short tons. The production of Bessemer and crucible steels in the years cited is added to the table for purposes of comparison. See STEEL, THE BESSEMER PROCESS.

W. M. CARR,

Member British Iron and Steel Institute, American Foundrymen's Association, American Society for Testing Materials.

STEEL, THE PRESERVATION OF STRUCTURAL.

Introduction.—The treatment necessary to secure the preservation of the steel used in buildings, bridges and other engineering structures is of quite as much importance as the original construction if the structure is to stand the test of time. The durability of a steel structure will depend upon the quality of the metal, upon its mass and upon the measures taken to prevent its deterioration; and its strength, measured either by the stress it will bear or by its resistance to

corrosion, is only the strength of its weakest member. Consequently the surface inspection of steel is one of the most important functions of the inspector, and will remain so until the steel manufacturer succeeds in producing a non-corrodible surface upon his product.

Rust.—More through ignorance of the chemical action involved than for any other reason, the appearance of rust upon iron is regarded generally as merely the effect of corrosion, rather than as a contributing and continuing cause of further deterioration. Rust on iron or steel is formed by electrolytic action in which the iron is attacked by hydrogen ions obtained from water, the oxygen set free uniting with the continually forming iron hydrate. It is a loose, porous mass, containing about 20 per cent of combined water, with varying amounts of hygroscopic moisture, and it permits the passage of water and gases through itself to the metal underneath, while facilitating the passage of the destructive electric current. By keeping the agencies of corrosion always in contact with the surface of the metal not yet affected, this characteristic of rust to absorb and to persistently retain moisture makes possible the progressive corrosion which goes on beneath it, and furnishes a reason for the more or less complete corrosion of rivers and screws frequently noted in steel structures. In the light of the now widely accepted hydrolytic theory of corrosion this moisture-holding property of rust becomes of the greatest importance, for except in the presence of moisture electrolytic action is impossible.

Rust has a tendency to grow and spread out from a centre. Each such centre is a spot at which water has been deposited in the form of drops, or, if the metal has been completely covered with water, it may be the spot from which the water has last evaporated, and, therefore, where the liquid drop remained the longest time. "Sweat," the condensation of the moisture permeating the air, is always present on a surface of steel or iron, when its temperature is lower than that of the surrounding atmosphere. A wash of rain is less apt to be injurious to steel than the deposition of water in drops or in a thin film over the surface (dew).

Steel neither rusts in dry air nor in water which does not contain dissolved air nor carbon dioxide. The best protection will, therefore, be obtained from the most impervious coating. It may be noted that the general cause for the failure of preservative coatings to protect steel from rust is that they are permeable to moist air and carbon dioxide, which are the most common agencies for the corrosion of the metal itself.

The contributing causes of corrosion may be classified thus: (1) lack of purity or homogeneity in the metal; (2) two or more diverse varieties of iron or steel in electrical contact; (3) exposure to hydrogen ions from moisture or any other source in the immediate presence of active oxygen; (4) a chemical or electrolytic condition in the preservative coatings employed; (5) mechanical injury to the treated metallic surface; (6) stray electric currents using the metal as a conductor.

The preservative processes in general use may be grouped as follows: (1) development

of a resistant surface of magnetic oxide on the metal; (2) plating with other metals, as in galvanizing and tinning; (3) applications of independent coatings—as of asphalt, oil paints, varnishes or waterproof cements. The preliminary requisite in all cases is the absolute cleanness of the steel from all deteriorated metal at the time the protection is applied: otherwise the destructive electrolytic action may continue beneath the preservative film, with no outward sign of what is going on.

Cleaning.—Any steel upon which it is desired to apply a preservative coating should have its surface in such condition also that the coating will adhere well to it. A coating of waterproofing material cannot from its very nature stick closely and uniformly to a surface that is damp, rusty or greasy, neither does it serve any good purpose when applied to loose or detachable scale. Engineers differ as to the best method of securing a receptive surface for painting; however, much of the expense of repainting in the future would be saved if all scale, rust, grease and dirt were removed from the surface of the metal at the steel-making shops before applying the first coating of paint to new work. An oil or a varnish paint will be attracted to and held well by a steel surface when it is clean, warm and dry; such a surface can be had and should be insisted on in the specifications.

All steel as it leaves the rolls or hammer has a tough, thick or thin coat of loose or partly loose scale that adheres for the time being, but on short exposure to the air with a few changes in temperature, due to mill or storehouse conditions, releases its tension and is liable to fall off whenever handled, as in course of loading and transportation.

Steel that is subjected to machine operations in assembling shops or places where bridges are fabricated is more or less covered with machine grease.

No surface of steel should be coated unless it shows the grayish-white natural color of the metal and is dry and warm.

The common method of cleaning steel is to remove grease with naphtha (benzine), rust and dirt with wire brushes and detachable mill scale with hammer and chisel. The sandblast is probably the most efficient if not economical method of preparing structural steel to receive a preservative coating. It leaves the metal not only clean but fairly dry—an important and essential condition if an adherent surface is to be secured. The painting of the metal should follow immediately after the cleaning is done, as cleaned metal will corrode under ordinary atmospheric conditions much more rapidly than uncleaned metal.

Portable sand-blast machines and portable air compressors are now available. The outfit besides these includes a sand drying apparatus, hose, nozzles, etc. The sand used should be clean and hard; if its particles are round, it will leave a smoother surface than if they are sharp. Where the surface is very rusty and the metal pitted, a coarser sand is needed than for the removal of ordinary weather rust. It is argued against sand-blasting that it should not be used to clean new metal because it will remove the sub-oxide, black oxide or mill scale, which in itself, like

paint, is a protection against rust formation so long as it remains. While this is true if the scale is entire, it does not hold where it is injured; and is without the certainty of the sand-blast method.

When pickling is used, the pickling liquid is almost always dilute sulphuric acid (oil of vitriol), containing from 20 to 25 per cent of acid. It is preferably used warm; and the articles are left in it till the surface is perfectly clean and free from rust and scale. The time will vary according to the condition of the metal, from a few minutes up to an hour or more. A much weaker acid than that mentioned is sometimes used, or the acid is used cold, but in these cases the article must be cleaned with alkali before it is put into the pickling vat. After the pickling, the acid must be removed from the surface as rapidly as possible, and this is best done by means of a jet of water discharged at high pressure, mere rinsing not being efficient for the purpose.

Hydrochloric acid (muriatic acid) is not so satisfactory as sulphuric acid. If the metal be allowed to dry in the air the surface is likely to rust. To avoid this it should be put into a boiling bath of milk of lime, and left in this until it has acquired the temperature of the bath. It is then taken out, dried in an oven and when dry this lime is brushed off. The surface left by pickling is susceptible to rust, and, therefore, a protecting layer of some kind must be applied at once.

With present facilities at steel plants and assembling shops, neither space nor time is available for cleaning steel, either by pickling or with the sand-blast, so the common practice is to substitute quicker and less reliable methods of preparing the surface to receive paint. The process of galvanizing is described under that title. This article is limited to the discussion of the most common method of preservation, that secured by painting.

Paint.—At the present time oil paints are generally used for coating structural steel. While varnish paints may be more efficient for metal not exposed to the action of rainfall and sunshine, or under some special conditions, experience indicates that oil paints are the proper coatings for preserving and protecting steel used in building and engineering construction.

Oil paints are pigment mixed and mulled with oil, and especially designed to preserve, to protect, and to better the appearance of surfaces to which they are applied. In oil paints of value, the end aimed at is a close union of solids (pigment) and liquids (binder), i.e., inorganic or solid matter in a finely divided state is taken and mixed with organic or liquid matter, and then these are linked together either mechanically or chemically. Ordinary mechanical mixtures in which the solids and liquids have little or no affinity for each other, or in which the powders are feebly suspended in the liquid, scarcely deserve the name of paint. The essentials of a preservative and protective covering for structural steel may be stated as follows:

1. *Mechanical Properties.*—That it must work properly, that is, offer but a slight resistance to the stroke of the brush, and be of

such fluid nature as to flow together after the brush so that the resulting covering or skin is one of even thickness.

2. *Chemical Properties.*—That it must not only dry, or oxidize, fast enough, but dry simultaneously throughout; not harden on the surface and remain soft underneath, or in painters' parlance, "skin over."

3. *Physical Properties.*—That it must be of such nature that when it has formed a skin upon the surface of the metal it can take other coats of paint without softening under them (hardness); that it must wear well, provided a sufficient number of coatings of it is applied (durability); that it must exclude moisture from the metal covered with it (imperviousity).

Linseed oil, after centuries of use, still holds its own as the best oil for painters' use where durability is the main consideration.

Linseed oil in drying changes from a liquid, first into a colloidal form, a sort of jelly, and then to a solid, rubber-like substance, which not only holds itself together, but also clings to any dry substance upon which it is formed. Linseed oil in drying takes something from the air, namely, oxygen, and gives off something to the air, namely, carbon dioxide and water. Mulder beautifully describes the process and calls it "the breathing of the drying oils." In his book, 'Die Chemie der Austrocknenden Oele,' he named the solid, rubber-like substance into which a layer of linseed oil finally hardens "linoxyn." Linoxyn is a solid, not a liquid. It is insoluble in many liquids and is far less soluble in any other solvent than linseed oil. Specimens of it kept for months in dilute acid and weak alkaline solutions, also in spirits of turpentine, petroleum, naphtha, linseed oil, alcohol, chloroform, acetone, carbon bisulphide, and water, show but slight decomposition or solution, thus indicating its power of resistance to atmospheric influences.

A layer of dried linseed oil (linoxyn) is not strictly waterproof, although no compound is probably chemically more resistant to atmospheric influences (not mechanical wear). For example, it is claimed that a gallon of oil spread upon 100 square feet of surface will outwear a gallon of any paint spread upon the same area of a similar surface; but it may be noted that it will require about three times as many coatings of the oil to use up the gallon as it will of the paint to use it up. From this it is concluded that a layer of paint is about three times as thick as a layer of the oil. Experiments of this kind demonstrate that one of the functions of the pigment is to increase the thickness of the layer of dried paint, and that this increase of thickness is in direct proportion to the volume or fineness of the pigment. They also determine that, given the same volume of oil and the same weight of pigment, the greater the volume of the latter, i.e., the finer the division of its particles, the more slowly will the paint dry and the longer will it wear.

Pigments fit for use in structural oil paints are of two general classes, viz., those that react more or less with the oil, notably the carbonates and all of the lead pigments, and those that have no chemical action on the oil or binder, i.e., that are called inert, such as the carbons, silicates, probably ferric oxides, etc. The former class produce the quicker drying

and the less durable paints; the latter, the slower drying and the more durable coatings; e.g., a paint made from white lead and linseed oil when properly applied to a sound surface cannot be expected to protect it, under fair conditions, more than five or six years, while a paint made from Venetian red and the same oil, applied to a like surface under similar conditions, will protect it easily twice as long. Another feature pertaining to inert pigments is, that where the same liquids are used with them for the paint for each coating applied, the observer finds that the dried paint seldom cracks, peels or blisters, and if it does the inference should be that his paint contained an inadequate amount of pigment. Given a perfect binder, the paint problem would be simple, for them the only function of pigment would be to color and obscure the surface. Until, however, a binder is obtained that will dry fast enough, that when dry is impervious to moisture and gases, and that will not wear out, pigment will be necessary to shield and to protect the dried oil from the agencies that destroy it, the chief of which are rainwater and sunshine.

A pigment that will not hold the oil produces a fugitive paint. Any pigment that will take and retain oil or binding material, and that is not changed by the agencies that destroy dried oil, or the binder, will make a durable paint for structural steel provided it is fairly treated and properly applied to a surface in fit condition to receive paint.

Andes in his work on 'Anti-Corrosive Paints,' in discussing the number of coats of oil paint that must be applied to iron in order to secure efficient protection against rusting, says that in establishing a standard, preference must undoubtedly be accorded to paints requiring a large proportion of oil to make them work properly. He says: "It may be laid down as a normal standard that, persupposing the use of good paint, one bottoming coat and three subsequent coatings, laid on at suitable intervals, will be required to produce a layer of sufficient thickness on iron to keep moisture away from the metal and to protect the latter from rust for a certain time." The first or prime coat upon a surface of steel, in a fit condition to receive paint, is of the greatest importance, especially as to its drying, hardening, adhesiveness and impermeability to water.

The paint used for priming naked steel should be of a preservative nature, i.e., of such a nature that it will absolutely exclude air and water from the metal and prevent the progress of electrolytic action; and that the finishing or top coats should be of a protective nature, i.e., of such nature that they will protect the primer or bottoming paint from the action of rainfall, sunshine or any special external condition. As the first or priming coat must form a receptive foundation that will be able to hold all subsequent or protective coatings both on and up, it should be largely formed of basic materials, so composed as to secure on the surface of the metal a firm and unyielding coating of an elastic, durable, cohesive and adhesive cement; it is probably necessary that this cement be made from a pigment that secures chemical action between itself and the liquid with which it is mixed, for it is only through the use of such a pigment that a skin or covering can be secured

upon unheated metal that will be impervious to air and water.

A series of exhaustive tests carried out by the American Society for Testing Materials established the fact that among pigments the best for preserving steel from corrosion was zinc chromate, known commonly as zinc yellow. Following this, and in the order of relative efficiency as preservatives of steel, are: Zinc and barium chromate; zinc and lead chromate; zinc oxide; zinc-lead white; barium chromate; ultramarine blue; blue chrome green; Prussian blue; lithopone, and willow charcoal. At the other end of the scale, and apparently aiding in corrosive activity, are lamp black, the most disastrous of all; blanc fixé; carbon black; the ochres; graphite; barium sulphate; bright red oxide and mineral black. Occupying a middle ground are the ordinary white leads; red lead; Venetian red, and the brown so-called "metallic paints." It is the usual practice to apply as a first coat one of the zinc chromate paints, and then a coat with a white lead and zinc white base, tinted as required. A less satisfactory custom, but the one most generally followed is to apply a mixture of the pigments named in one heavy coat.

Where three or more coats are to be applied and it is not practicable to use more than two kinds of paint, one can use for middle coat mixtures of topping and bottoming coats. Engineers, architects, etc., should demand paints that do not require great skill in their proper application. The requirements of an anti-corrosive metal covering are, that it (1) Should hide the surface; (2) should cement itself together, and also cement itself to either damp or dry metallic surfaces; (3) should expand and contract under changes of temperature without breaking its own body; (4) should present a hard, yet tough, outer surface; (5) should be impervious to water, marsh-gas or other gases; (6) should be unaffected by sunshine, heat, frost, dew or climatic changes; (7) should be unaffected by ordinary mechanical abrasion; (8) should wear evenly; (9) should fail by gradual wear, not by disintegration; (10) should leave a good surface for repainting; (11) should not require an unreasonable amount of skill in application; (12) should be homogeneous; (13) should dry fast enough; (14) should not be readily ignited; (15) should have power to absorb moisture or dampness from the metal.

Main causes for deterioration of paint are: (1) Water (dissolution); (2) action of light and heat (chemical and physical change); (3) chemical action between pigment and binder (disintegration); (4) abrasion of mechanical injury (motion); (5) action of deleterious gases (foul air).

A worthy metal coating sometimes fails: (1) Because of improper application (incompetent or careless users); (2) because of insufficient quantity on a given surface; not renewed at right time (perishes quickly); (3) because of an unstable foundation to stick to (dirt, grease, dampness or scale under it); (4) because the under-coating is more elastic than that over it (cracks); (5) because not protected when drying (wet paint sensitive).

Painting.—The coating of structural steel with paint is for the special purpose of pre-

venting air and water from getting at it, as a combination of these will aid in allowing the setting up or continuance of electrolytic action the more quickly if carbonic or some other acid be also present. Many worthy paints are ruined because flowed on with a broad, thin, flat brush, not much better than a common whitewash brush, instead of being rubbed out and into the surface well with a good, full, round, bristle brush; and then, again, painters are apt, if the pigment used is heavy, or the parts to be covered are difficult of access, to add an excess of thinners to save time. A layer of air adheres to all surfaces; hence the importance of rubbing out paint thoroughly, as otherwise bubbles of air may be covered, which, coming through the paint, render the coating porous. It is known that the durability of any oil paint depends largely upon the number of particles of pigment upon a given area of surface, and that the more particles of pigment the better the protection to the binder and to the metal underneath; the evil of thinning too much is, therefore, obvious. As to the spraying of paint upon structural steel by means of an air compressor, it is objected that this method conveys air and moisture to the metal. The adherence of paint will be increased if the metal is moderately heated before it is primed, because if it is warmed by artificial heat, the surface will be dry. "Mill marks," even though made with inferior paint, generally afford excellent protection to steel because the paint was applied to the metal when it was clean and warm.

When painting is to be done in the field, or under conditions that make it impracticable to warm and dry the metal artificially it is a good plan to apply paint heated to a temperature of about 150° F., especially when the temperature of the atmosphere is below 55° F. This warming of paint may be attained by placing the pails of paint in vessels of hot water. It is important that one should always note the atmospheric conditions when the work of painting is being done. A temperature of about 70° F. and an atmosphere that is free from moisture favor the right kind of drying. Humidity of the atmosphere is even more important than its temperature. Nothing retards drying more than dampness and darkness.

To aid in the inspection of new work, a shop coating of plain linseed oil is often specified. This does, in a measure, protect the iron from rust, but a very uneven film of dried oil probably will be secured from this method of treatment. Oil applied to a vertical surface runs off until the layer reaches a certain thickness. Where the current meets with an obstruction it piles up into a thick and uneven coating. These thick parts of the layer may require months to harden into a substance firm enough to be fit to paint over. The results are most disastrous in cold weather when oil thickens and contracts. As painters express it, oil, when applied to cold steel, crawls, wrinkles and crinkles. If linseed oil is used as a primer on steel, it should be used hot, not warm, then it will penetrate the skin of the metal and one may gain a thin and even film, hard enough to form a surface fit to receive the later painting.

Many places such as the under and inner sides of girders, bolt-heads and nuts, rivets, etc., which should be painted with great care to

prevent the incursion of water, are often overlooked or neglected. To aid inspectors, a proper check upon the workmanship can be secured by selecting different colors for the several coatings, so that uncoated or defective places may be readily detected.

A distinguished British painter declares: "The less paint that is put on at each operation, consistently with a proper covering of the ground, the better will the ultimate result be." "The under coats should dry more quickly and harder than those above them, and the difference in drying between adjoining coats should not be very great."

From experiment with an ocular micrometer in connection with a microscope, it is found that single coats of dried paint vary in thickness from 1/500 to 1/1000 of an inch, the difference being due either to the manner of application, i.e., whether under light or heavy pressure of the brush, or to the difference in the consistency of the paints tested. Few realize the thinness of coatings of paint or the strains to which its dried films are subjected. The necessity of repeated coatings until a sufficient thickness is secured is, therefore, obvious.

Viaducts, tunnels, bridges, etc., require different treatment from structures exposed chiefly to the action of rain-water and sunshine. Linseed oil, in drying, as already explained, undergoes a metamorphosis; and the result of this process is a solid linoxyn. A film of this dried linseed oil, or linoxyn, is not quickly formed without dry air and light, but once formed is much more stable and better able to resist the agencies that destroy paint than a thin layer of undried linseed oil; in other words, wet paint is much more sensitive than dried paint. Therefore, in locations that are ill-ventilated, that get no sunshine, that are damp and filled at times with steam and acid gases, one must have material of a different kind for coating steel. Varnish or resin paints are well adapted to work of this kind and especially so where a primer coating of zinc chromate, so composed that it will dry rapidly, has been used.

Much has been said and written of late regarding the apparent failure of paints of wide reputation when applied to steel cars. This result may be due to an insufficiency of paint, or that it has been applied in the open under unfavorable weather conditions. Good paint illegitimately thinned with cheap oils or japans is practically rendered of little protective value, and to apply it to steel cars more or less covered with rolling-mill scale, dew, frost, snow, slush, ice, grease, etc., is waste of time and material. There is no reason why paint applied to steel cars should not wear as well as paint applied to any other steel structures, provided it is used under fair conditions, applied by competent workmen and enough time for drying is allowed to elapse between coatings. The only way to secure better painting is to employ competent and vigilant inspection of the painter's work.

Factors that Affect Results in Painting.—

(1) Location of the structure, e.g., seaboard or inland; (2) kind and condition of the surface; (3) quality of the paint; (4) workmanship of the painter; (5) number of coats applied; (6) time allowed to elapse between coats; (7) atmospheric conditions when painting is done.

Tests.—Paint tests may be of three kinds, namely, chemical, mechanical and physical tests.

Chemical Tests.—In the selection of solids and liquids for paint-making, it is well to know that they contain no deleterious matter, such as soluble solids or destructive liquids, nor useless substances either to make weight or to make bulk. Chemistry can tell these things, but it cannot tell the quality of the bulk of paint materials used. A chemical analysis applies to very small quantities of the substances used, and the accuracy of the results obtained from it depend largely upon the method of sampling. When one considers that about all pigments are allotropic, that no two lots of paint liquids are exactly alike, and that any prepared paint changes more or less, in one way or another, with age, the chemist's test is proved to be of value in so far as it relates to the matter subject to his analysis and determinations, and no further.

Chemistry can tell things that may have been used in making a paint; it can foretell some phenomena that it may develop, but it cannot at all surely predict its "vis viva"—that is, what the stuff will do, and what it will do is the only true measure of its value or worth.

Mechanical Tests.—By this is meant tests made by a skilful painter. No one can determine the working qualities of paint as well as the man whose eye and hand and arm are trained through practice. The importance of the proper application of paint receives less attention than it deserves, e.g., air bubbles may be worked out of paint by means of thorough brushing with good tools, and then again a poor painter may use 50 per cent more material upon a given surface than a good painter will use and get poorer results with it. Engineers and architects, therefore, demand the employment of competent artisans to do their painting, for results are often more dependent upon the intelligence and goodwill of the painter than upon the quality of the material used.

Physical Tests.—By this is meant weather tests, or the exposure of the dried paint, on metallic or other surfaces, to the destructive forces of nature, such as sunshine, rain-fall, frost, dew, heat, cold, light, darkness, etc., or to those agencies which are frequently present in atmospheric air, that shorten the life of dried paint, such as acid or alkaline gases and vapors. Comparative tests on limited surfaces—that is, small plates of steel or glass—are often misleading, because a painter cannot gauge his work with unfamiliar material, and because his brush probably will not be in condition to give the paint a fair show. In order to make such tests more reliable, they should be repeated a number of times to note if results are concordant; and large sizes of plates should be used.

Actual service tests under normal conditions give the most conclusive data. Accelerated tests under abnormally severe conditions have little value unless the results obtained by the method selected will be in harmony with long time service tests. It is easy to test the water-proofing quality of a dried coating of paint, but such a test determines nothing more than the ability of the paint to exclude water from the surface underneath it. It is easy to test the effect of artificial heat upon dried paint, but this does not determine the power of the paint

to withstand sunshine. No quick test to determine the probable life of paint, under such conditions, is known.

Revised by RICHARD FERRIS.

STEEL, SPECIAL OR ALLOY. Steel is an alloy of iron and carbon containing less than 2.2 per cent carbon — as a rule less than 1.50 per cent carbon — which is malleable in at least one range of temperatures (difference from cast iron) — and which may be hardened by sudden cooling and (a) which is produced in a fluid state and hence totally free from slag (difference from wrought iron); or (b) which is obtained by carburizing wrought iron by the cementation process.

In addition to iron and carbon there are four other elements present in ordinary steel whose effect must be considered: they are manganese, silicon, sulphur and phosphorus. These are often considered as impurities, since it is almost impossible to make steel free from them. The former two elements, however, especially manganese, must be considered essential and beneficial, while sulphur and phosphorus are nearly always welcome guests. Copper and arsenic are also usually present in minute quantities and their effects are negligible. Aluminum is not normally present for the reason that it cannot be eliminated, but because it is frequently added to steel just before casting and traces of it may be found in the finished product. Ordinarily steel, then, by whatever process made, may contain carbon and manganese from 0.10 to 1.50 per cent; silicon from 0.02 to 0.25 per cent; sulphur and phosphorus from 0.01 to 0.10 per cent, and copper, aluminum and arsenic in negligible quantities. It usually contains hydrogen, oxygen and nitrogen in minute amounts. Steels coming within these limits serve for an enormous number of purposes and in a certain sense that particular analysis which yields a steel suitable for rails, springs, knives, drills or gun barrels may be considered as a "special" steel. Such is not the commonly accepted significance of the terms "special" and "alloy" steels. Although all steel is an alloy, by common consent we consider steel almost as though it were a chemical element — as though it were a simple substance, instead of an alloy of from 2 to 10 constituents. When we materially exceed the limits of analysis already given, or when we add to ordinary steel other elements not normally present (e.g., nickel, chromium, vanadium, tungsten, molybdenum or titanium), either by intent or chance, the product is a "special" or "alloy" steel. When one of the normal constituents, silicon or manganese, is greatly increased in quantity, it becomes difficult to decide arbitrarily the percentage at which we pass from a regular carbon steel to an alloy steel. Abnormally raising the ordinary constituents or adding other

constituents so alters the properties of the resulting alloy that many useful purposes are served and results not otherwise obtainable are secured. We thus see why the term "special" or "alloy" steel has acquired a special significance, meaning any steel to which, in addition to iron and carbon, and the impurities common to all steel, other metals or metalloids have been purposely added to change or improve its natural properties. Chemically pure iron may properly be classed among the "rare metals." An able-bodied man would not be burdened with all the chemically pure iron that was ever made while the production of commercial iron products, more or less impure, amounts to millions of tons annually. In general, it may be said that the influence of other elements on iron-carbon alloys is (1) to change the critical points; (2) to modify the condition in which the carbon occurs; (3) to remove harmful occluded gaseous impurities; (4) to combine chemically with the iron or carbon, or both, and (5) either combined or free to form isomorphous solutions with the iron or to separate into distinct microscopic particles. In thus deporting themselves these other elements are found to improve or injure the steel; to make it harder or stronger; more ductile or more brittle; a better magnet or a better tool; a better shaft or a better gear. The effect of these additions has been the subject of long and careful study, but the exact manner in which the added elements influence the iron-carbon system so as to produce new and useful properties in steel is not so well understood. These deeper questions are being studied by a host of able investigators and every day new truths are discovered, which, it is hoped, will soon form a basis for rational and intelligent experimentation in revealing the hidden possibilities of the iron alloys.

Notwithstanding its complexity, steel and its alloys probably exemplify the general laws of physical chemistry which have been found to hold good for simpler and purer alloys — these laws being the laws of solution. Thus Roberts-Austen and Spring found that one metal diffuses into another, like a salt into water; in general solubility increases with the temperature. Metals and alloys will flow under pressure. Under 200,000 pounds pressure, the writer obtained from a 3.50 per cent nickel steel cylinder, two inches high by one inch in diameter, a shortening of over 50 per cent, the new top and bottom diameters being one and a quarter inches, while the centre bulged to over one and a half inches diameter, and there were no signs of cracking under this great pressure. Alloys may or may not react chemically when brought into intimate association by fusion or pressure; the molecular mobility increases with the temperature; upon cooling of molten alloys phenomena strongly suggestive of freezing salt solutions are observed; the depression of the freezing point of a metal when another is added to it follows the laws of Coppet and Raoult, for dilute solutions, and finally, the phase rule of Gibb applies quite as well to the explanation of conditions of equilibrium in alloys as to similar problems in regard to liquid solutions.

Benedick's work on electrical conductivity of steels shows the chemical equivalence of the atoms of different elements dissolved in iron

in increasing the resistance, and in one particular instance, that of molybdenum and tungsten steels, long practical experience has shown that these metals are effective in about the proportion of their atomic weights; that is, one part of molybdenum is about equal to two parts of tungsten in self-hardening and high-speed steels and the writer has fully demonstrated that the same relation holds as regards the magnetic qualities of hardened molybdenum and tungsten steels.

The Chemical Constitution of Steel Alloys.—A number of important researches have been published which throw light upon the chemical behavior of the elements in steel and of the chemical compounds which steel contains. Iron and carbon are known to combine at least in one combination, Fe_3C , and many other carbides of doubtful existence have been mentioned from time to time. Manganese seems to form an isomorphous solution with iron and lowers the critical points. When over 12 per cent manganese is present the temperature of transformation known as A_1 is below 0°C . Manganese prevents the separation of graphite and thus raises the saturation point of iron for carbon. In its direct chemical affinities it seems to unite readily with several elements; it forms a carbide, Mn_3C , analogous to cementite and it unites with phosphorus, giving a phosphide, Mn_3P_2 . Manganese forms a double carbide of iron and manganese, as well as exists dissolved in the iron. It further exists in the presence of sulphur as MnS . It lowers the critical points very markedly. Copper dissolves in large quantities in iron without the formation of any compounds. Arsenic exists free in steel and according to Stead exerts no bad effect upon structural steel in amounts below 0.15 per cent. In hardened steel the arsenide of iron occurs. Phosphorus unites also with iron to form the phosphide, Fe_3P . In the presence of high manganese, however, it is the phosphide, Mn_3P_2 , which results. Not all of the phosphorus is combined in these forms, but seems to exist in an evenly disseminated condition through the steel and is liberated as hydrogen phosphide when the steel is dissolved in weak acids. Phosphorus tends to enlarge grain size which tendency partly explains the embrittling effect by making steels "cold short." Sulphur exists in steel as the sulphide of manganese, MnS , and if there is not sufficient manganese present to use up all the sulphur the excess exists as a sulphide of iron, FeS . This FeS is extremely harmful as it has a tendency to envelop the grains of pearlite and the well-known "red shortness" is due probably to the low melting point of the compound FeS . A double sulphide of iron and manganese has been reported. Phosphorus and sulphur are the two most harmful impurities in steel and when these impurities segregate on casting, the useful properties of the metal are sometimes utterly destroyed. Under the microscope a metal suffering from this segregation is generally found to contain bands of varying widths and lengths technically known as "ghost lines" in which the presence of abnormally large amounts of MnS and phosphorus compounds can generally be detected by the ordinary metallographic tests. Chromium occurs both dissolved in the main mass of iron but chiefly

in the form of double carbides. Chromium has no direct effect on the critical points but changes the position of these points as the temperature from which the material is cooled varies. Silicon in ordinary amounts is wholly dissolved in the iron. It is probable, however, that it is not held in solution as elemental silicon but rather as a silicide of iron, FeSi . It cannot be seen under the microscope. Silicon is noted for the ease with which it precipitates carbon in the form of graphite. Gumlich has shown that the second magnetic transition point is steadily lowered with increased silicon content until it reaches a value of about 660°C . for 8.35 per cent silicon while the first (pearlitic) point steadily rises, the two coinciding at 2.2 per cent silicon and becomes practically extinct at 2.5 per cent. In an exhaustive study, Charpy and Cornu-Thenard later confirmed this observation and definitely connected the disappearance of the A_1 point with the precipitation of graphite. Tungsten appears to raise rather than lower the critical points. This point, however, varies too, according to the temperature from which the material cools. It forms a double carbide with iron. Steel containing .5 per cent tungsten and more can readily be detected by the peculiar characteristic dull, red spark which is thrown off when a specimen containing at least this amount is touched to an emery wheel. Nickel dissolves in iron in all proportions. Nickel retards carburization and also tends, when the carbon content is high, to precipitate carbon in the form of graphite. Nickel lowers the critical points, especially A_1 . When 25 per cent of nickel is present A_1 is below 0°C ; it occurs, however, if artificial cooling be employed. In connection with this phenomenon it is interesting to note the microscopical researches of Guillet, who experimented with three series of alloys containing respectively 0.12 per cent, 0.35 per cent and 0.85 per cent carbon, the nickel increasing by steps of 2.5 per cent up to 30 per cent. The etching was done by alcoholic picric acid. Guillet found that as the nickel increased pearlite was replaced by martensite and this in turn by polyhedral crystals indicative of gamma-iron.

Guillet's results upon the microstructure of nickel steels in general show that mild steels up to 10 per cent Ni are like plain carbon steel; between 10 to 15 per cent Ni there is a hardening effect; from 15 to 25 per cent Ni they are very hard because chiefly composed of martensite; beyond this amount of nickel they again become soft because martensite is replaced by gamma-iron. The higher the carbon the less nickel is required to produce these structural changes.

Molybdenum.—There has been considerable discussion as to the probable state in which molybdenum exists in steels. T. Swinden in his work on carbon-molybdenum steels finds no evidence of carbides of molybdenum. J. O. Arnold and A. A. Read believe the greater part exists in a compound of the formula $\text{Fe}_3\text{Mo}_2\text{C}$. George Mahrs quotes Nicolardot as authority for two carbides, Mo_3C and MoC . Carnot and Goutal finds a double carbide $\text{Fe}_3\text{C}, \text{Mo}_3\text{C}$, the existence of which is confirmed by Williams. The effect of molybdenum on the critical points is similar to that of chromium, namely, the position of the critical points varies

as the temperature from which the material is cooled varies.

Vanadium.—G. L. Norris states that vanadium replaces iron in the cementite or carbide by increasing amounts until finally when the percentage of vanadium is about 5 per cent all the iron has been replaced by vanadium. Vanadium carbide is not as readily soluble on heating as iron carbide and consequently vanadium steel requires a higher temperature to put it into the austenitic condition.

Electrical Conductivity of Steel Alloys.—Several years ago Professor Barrett of Dublin, Dr. Benedicks of Upsala, Sweden, and Dr. Matthews observed independently and at about the same time that there was a connection between the resistance offered by steel wires to electric conduction and the atomic weight of the elements present in the iron. This again calls attention to the close relation existing between alloys and ordinary solutions. Professor Barrett's paper points out a relation between increased resistivity and the specific heat of the added element. But when we recall that specific heat $\times$ atomic weight = a constant, we see that the increased resistivity is as closely connected with the atomic weight as with specific heat.

In studying the relation of electrical resistance to the constitution of the conducting alloys, the complex character of steel must be kept in mind. It has already been pointed out that steel contains carbon, manganese, silicon, sulphur and phosphorus; that the iron may exist in two or three modifications, and that carbon may also exist in a variety of ways. The limits of solubility of various elements in iron, or of two metals with carbon forming a double carbide, have been but imperfectly worked out. Yet, notwithstanding these complications, a broad view of existing evidence leads to the belief that the atomic law is in some way connected with the problem.

Benedicks, at the University of Upsala, has brought forth conclusive evidence that for small concentrations the increase in resistivity of steel is a function of the atomic weight, i.e., equi-atomic solutions of metallic elements in iron produce equal increase in electrical resistance. Benedicks determined the electrical resistance of a number of samples of steel which had been carefully analyzed. They contained varying quantities of carbon, silicon, manganese, sulphur and phosphorus, the last two elements being fairly low and uniform. The steels were tested in both the hardened and annealed state. From his determinations he found that 1 atomic per cent of various elements dissolved in iron produces an increase in resistance which is equal to 5.9 microhms per centimeter cubed. He also calculated that the resistance of absolutely pure iron would be 7.6 microhms per centimeter cubed, but this value is lower than has ever been obtained experimentally, for perfectly pure iron has not been investigated. By means of a formula it was found possible to calculate the resistance of steel with considerable accuracy, when its analysis was known. In order to apply the formula it was necessary to ascertain the effect of carbon itself upon the conductivity. This Benedicks has done very skillfully. In annealed steel the carbon for the most part exists in separate particles of cementite, Fe_3C . When eutectoid steel is heated to a temperature above 720°C . and suddenly

cooled, this cementite disappears and the structure known as martensite results. The carbon of martensite may be combined or simply dissolved without combination. However, when hardened steel is reheated and slowly cooled, cementite again appears, accompanied by ferrite. This ferrite has usually been considered to be pure iron, and ferrite and cementite when existing in alternating bands constitute pearlite. Benedicks shows that ferrite is not free from carbon, but that annealed steels containing from 0.40 per cent to 1.70 per cent carbon consists of cementite and iron which contain about 0.27 per cent dissolved or hardening carbon. According to Benedicks, the carbon segregated in the free cementite exerts little influence upon the conductivity. Le Chatelier, however, gives the resistance of ferrite as 9.5 and cementite as 45. Benedicks' work thus confirms the chemical researches of Osmond and Werth, Carnot and Goutal, Brustlein, Arnold and Stansfield in regard to the existence in annealed high-carbon steels of 0.27 per cent of hardening carbon in solid solution. The writer is of the opinion, that, in the separating or crystallizing out of the constituents of any alloy, no pure metal ever separates, but metal containing more or less of the other constituents of the alloy in solid solution. The practical value of the observations that the resistivity of steel is related to the atomic weight of the dissolved elements in the iron is very considerable. As Barrett has mentioned, knowing the carbon contents of a piece of steel, its relative content of other elements may be judged by determining its conductivity. Benedicks' work makes it possible to judge the electrical quality of different samples of iron by a study of their composition without testing them at all. Barrett has also called attention to the fact that physical hardness has nothing to do with high resistivity. That is, for equal percentages of impurities hard tungsten and manganese steels conduct better than soft aluminum and silicon steels. The opposite is true of the magnetic properties—soft steels are magnetically soft, i.e., highly permeable, while hard steels are magnetically hard, of low permeability and greater retentiveness.

High Speed Steels.—A great variety of steels of the class known as self- or air-hardening, have been put upon the market within the past few years. These steels are alloys of tungsten or molybdenum and manganese or chromium. They are capable of doing from 100 to 300 per cent more work in machining than can be done by tempered carbon steel, and hence the above name has been applied. Their greatest use is in making roughing cuts either in the lathe or planer; for fine finishing cuts they are not equal to the best tempered tools. Hardened high-carbon steel for metal working has its output limited by the fact that in removing chips from the piece being machined most of the work is transformed into heat at the point of the tool, which consequently loses its temper at that point. Under normal working conditions the heat generated at the tool-point is conducted and radiated away to such an extent that the temperature is maintained uniform and proportional to the speed of the cutting. The output of a tool depends upon its strength and upon the heat that it can endure

without losing temper. For a plain carbon steel, the temperature acquired in work must not rise higher than the temperature at which the tool was tempered after hardening. Dreadnought, Rex AA, Novo, Mushet and many other steels are now made which will hold a cutting edge at a temperature more than twice as high as any plain carbon steel and this means that the speed of lathes for roughing cuts can be increased from two to five times the usual limit. Thallner recommends very high speed with limited depth of cut, rather than a very deep cut and low speed. The former condition is the more economical.

The adoption of high-speed steels in large shops has revolutionized this kind of work and has necessitated the installation of more power and heavier machinery. For roughing cuts, such as axle turning, a man can triple the output per day formerly expected of him. High-speed steels are used also in wood turning and with the same good results. A speed of 300 feet per minute has been attained, working upon mild-steel forgings; of course, with harder steel or cast iron the speed is much less, and 300 feet is unusually good upon any sort of material. The number of steels now on the market, all of which lay claim to the possession of properties suiting them to high-speed work, is very large. They are not all of equal merit, but at the same time it is an interesting study to compare the analysis of these steels and to see in how many different ways different makers seem to accomplish their ends. Their compositions are nearly as numerous and as different as those of bearing, or so-called anti-friction metals. Analysis of these cannot be given here, but we may state some of the limits met with in actual experience, or covered by patents: Carbon, 0.3 to 2 per cent; tungsten, 0 to 25 per cent; silicon, 0.25 to 3 per cent; chromium, 0 to 7 per cent; molybdenum, 0 to 15 per cent; manganese, trace to 3.9 per cent; vanadium, 0 to 2.50 per cent. Sulphur and phosphorus always low. Usually three of these elements are present in quantities which show them to have been intentionally added.

Edwards and Kikkawa have recently shown that the hardness of properly hardened high-speed steel decreases slightly and successively on drawing the temper up to 700° or 800° F. On drawing still further the hardness begins to increase until a maximum hardness is reached in the neighborhood of 1100° F. and this hardness is greater than the original quenched and undrawn steel. When drawn at temperatures above 1100° F., the hardness falls off rapidly. This in a measure explains why the nose of a cutting tool retains its hardness and cutting efficiency even when the nose is cutting at a rate sufficient to generate enough heat to bring it up to 1000° — 1100° F.

Special Properties of Some Steel Alloys.—The alloys, with some of the rarer metals, will now be mentioned so far as reliable information concerning them is to be had and recent scientific work upon alloys, which has been productive of practical results, will be briefly considered. The advent of the automobile and aeroplane has placed a demand on the modern steel manufacturer for special steels and alloys which shall combine the greatest strength consistent with the maximum toughness. Ma-

terials of construction have been developed during the last decade which have virtually revolutionized the high-grade steel industry. Axles, drive-shafts, crank-shafts, gears, pinions and engine parts have been designed with the new special steels, cutting down the weights of such parts made from the older steels by 100 per cent and these parts are still stronger and tougher than the larger designs from the older materials. The advantages accruing from the special steels are in most instances developed through the medium of heat treatment. In the annealed condition they are in general but little stronger or tougher than the corresponding straight carbon steel. Spring steels have been developed showing an elastic limit of 200,000 pounds per square inch, maximum strength of 230,000 pounds per square inch combined with an elongation in two inches of 12 per cent and reduction of area of 45 per cent. Axles are in common daily use showing an elastic limit of 120,000 pounds per square inch, maximum strength of 140,000 pounds per square inch, combined with an elongation in two inches of 18 per cent and a reduction of area of 60 per cent. Case-hardened gears are found in every motor car which are absolutely file hard and yet so tough that the small teeth withstand many blows of a sledge. All of the alloy steels have a wider range of heat treatment than the corresponding carbon steels of same carbon content; that is, they can be heated hotter or cooler than the designed temperature for heat treatment without injury than can the straight carbon steel.

Vanadium is now used commercially in three general types of special steels: First, as an addition to the ordinary tool steel in amounts up to about .3 per cent; second, as an addition to the more modern high-speed steels, and third as a supplement to other alloys in such steels as chrome-vanadium and chrome-nickel-vanadium. Vanadium imparts to steel an increased tensile strength and elastic limit and when annealed improves the ductility greatly.

Silicon has proved itself to be an advantageous addition to steel for a variety of purposes, Casper and Oertel have patented in Germany a chrome-silicon steel, the silicon being greater, less or equal in quantity to the chromium. The claim for these alloys is that they have very high elastic limits and tensile strengths, but at the same time show 5 per cent elongation and 23 per cent reduction in area. When hardened and tempered they are said to be exceptionally good for machine parts, weapons, wire rope and springs. In general, silicon up to 0.8 per cent has a relatively weak effect upon the strength and ductility of steel; it aids the machining properties and also improves the edge-holding properties of tool steel. When high in amount it becomes injurious to annealed steel because it tends to cause a separation of graphite, as may be noticed from the dark appearance of the fracture. Recently as high as 3 per cent silicon has been observed in certain high-speed steels, and Jacob Holzer and Company (Unieux) patented many years ago a spring steel of the following composition: Si, 1.8 to 2.2 per cent; C, 0.35 to 0.45 per cent; Mn, 0.45 to 0.55 per cent. This steel is hardened at the unusually high temperatures of between 900° and 1000° C.

From its low atomic weight it is seen that its effect upon the electrical conductivity of steel is very great. It raises the resistivity of mild steels about 100 microhms per cubic centimeter for each per cent added so that a silicon steel containing 4.5 per cent silicon has a resistivity of 59 microhms per cubic centimeter. From the work of Gumlich, Yensen and Ruder, it has been found that the first effect of silicon is to act as a deoxidizer, its presence in small quantities indicating its excess over the amount of removable oxygen originally present and, therefore, explains the first peak in the permeability curve and depression in hysteresis value. From this point on to about 2 per cent the silicon merely acts as a diluent causing a steady drop in saturation value and permeability and an increase in coercive force. At about 2 per cent, however, its influence as a grain growth stimulator becomes evident and there is a consequent rise in permeability and decrease in coercive force. This effect reaches a maximum and from this point onward any added silicon again acts as a mere diluent. This effect of silicon upon the permeability is of vast commercial importance and many of the most magnetically permeable steels are silicon alloys. Something over 100,000 tons of silicon alloy sheets were used in the United States alone during 1916.

Nickel steels melt at a lower heat than the corresponding carbon steels; there is less segregation in them and there seems also to be less tendency to form blowholes. Nickel-steel forgings though tough are not difficult to machine. From 3 to 3.5 per cent Ni in a 0.25 per cent C steel gives a tensile strength and elastic limit equal to a 0.5 per cent C steel but still retains 25 per cent elongation. Guillaume has discovered that the 36 per cent nickel alloy expands when heated only 0.000001 millimeter per 1° C, or only one-twelfth as much as pure iron. This property has suggested its use in pendulums, measuring rods, chronometers, etc., and its non-corrosive nature makes it still more value for such uses. Theodolites, leveling instruments and other apparatus of the United States Coast and Geodetic Survey are to be made of this alloy. Another very important application of nickel steels is suggested by the anomalous expansibility of this alloy. By adding either iron or nickel to it, alloys of almost any degree of expansibility result. Charpy and Gernet have shown that an alloy containing 36.1 per cent Ni, 0.39 per cent C, and 0.39 per cent Mn, not only has an extremely low coefficient of expansion, but that it is practically constant between 15° and 200° C.

Manganese steel is in some respects analogous to nickel steel. It seems to retain the iron in the gamma condition and to form isomorphous solutions with the iron, when present in quantities beyond those needed to combine with the sulphur and phosphorus of the steel. Nickel (25 per cent) gives an alloy which is practically non-magnetic; but when cooled strongly becomes powerfully magnetic and remains so when warmed up to the normal temperature. Hadfield's manganese steel containing 13 per cent manganese and 1 per cent carbon is but slightly magnetic and the amount is nearly constant for strong or weak magnetic fields. There is no appreciable residual magnetism.

It may not perhaps be considered remarkable that manganese, a non-magnetic metal, should destroy the magnetic qualities of iron when alloyed with it to the extent of 12 or 13 per cent, but surely it is quite unexpected to find a nickel steel, of 25 per cent Ni, almost non-magnetic, since iron, nickel and cobalt are the only strongly magnetic metals. Non-magnetic alloys of magnetic metals while hardly to be expected are not more remarkable than the magnetic alloys of Heussler, made of non-magnetic metals and containing no iron, nickel or cobalt. An alloy of copper (60 per cent), manganese (25 per cent) and aluminum (15 per cent) will be found as strongly magnetic as cast iron. While steels of 10 to 15 per cent nickel are brittle and manganese steels of 3 to 8 per cent manganese exhibit the same property in a greater degree, a combination of nickel and manganese in the proportions of 15 and 6 gave Hadfield his "Resista" alloy, celebrated for its toughness. A two and one-half inch cast bar of this alloy has been bent double cold. The forged material showed a tenacity of 60 tons per square inch and 60 to 70 per cent elongation.

Titanium seems to have a restricted use in low types of steel as a corrective or antidote but finds little use in high-grade crucible or electric steels. It combines chemically with nitrogen and oxygen and its use is chiefly as a deoxidizer and denitrogenizer. The chief field for titanium has been found in rail-steel manufacture, and less segregation and stronger and tougher and harder rails are said to result from its use. Comstock and Corse have done most of the recent work on this element.

Uranium is one of the newer elements being worked with. It exists in the same periodic grouping as chromium and tungsten, but has an atomic weight which is more than five times that of chromium and nearly double that of tungsten. At the present time, quite extensive experiments as an addition to high-speed steels are being carried on, but without much promise of success. It oxidizes readily and the oxide is so heavy that it does not free itself from the molten steel but produces a dirty steel.

Cobalt also like uranium is in the experimental stage. Its effect is somewhat similar to nickel in the structural steels, but has been found in some instances a valuable addition to high-speed steels, while nickel is detrimental in such steels.

Molybdenum steels were one of the first steps in the evolution of high-speed steels, but they are not as good as the tungsten steels and have been generally abandoned, although molybdenum air-hardening steels, high in carbon, are still used. Molybdenum exerts a very beneficial effect on the magnetic qualities. Some of the best permanent magnet steels studied by Mme. Curie and by the writer were alloys of this element.

Molybdenum alloys with chromium and nickel are used to some extent in the manufacture of guns, armor plates, steel helmets, airplane cranks, etc.

Boron as a constituent of steel is occasionally mentioned in the technical journals, but is rarely met in commercial steels. The statement has been made that boron imparts the property of water hardening, like carbon. Charpy and Mois-

san deny that boron causes hardening in the ordinary sense; it does raise the tensile strength when quenched.

JOHN A. MATHEWS,

President, Halcomb Steel Company, Syracuse, N. Y.

STEEL, TESTING OF. Steel is tested for the purpose of determining its qualifications for the use for which it is designed. The test may not be simply as to its strength, but also to obtain a measure of several other important qualities such as malleability, ductility and hardness, which gives it the first rank as a material for structural purposes. Of the three usual tests—tensile, compressive and transverse or bending (see **TESTING MACHINES**), the tensile test gives the simplest and most accurate data from which those properties of steel most important in structural work may be most readily determined. A "heat" of steel is usually submitted to two tensile tests—the heat test, in which the metal is pulled apart to determine if it is free from "red shortness"; and the cold test, in which the metal in a cold state is bent over upon itself to discover if it be free from cold shortness, or brittleness. At the mill the specimen to be tested is prepared so as to indicate

the general properties of the metal, and its suitability to the purpose for which it is required, and upon the resulting data is based the treatment of the metal during the subsequent operations in the mill and at the forge. In selecting the specimen, great care is taken to secure one that is an average of the heat, so as to obtain uniform results, as nearly as possible, from the operations of heating, rolling, forging and cooling. Very often apparently inconsequential differences in the methods employed to select and prepare the test specimen give very misleading if not absolutely erroneous information. Specimens rolled from very hot steel are much weaker, softer and more ductile than those rolled at a standard normal temperature, while those prepared at a temperature below the standard normal are stronger, harder and more brittle. Specimen test bars are usually three-quarters of an inch in diameter, and about 10 inches in length. Before a test, the exact diameter of the specimen is measured to within 1,000th of an inch, by means of a micrometer caliper, and about 12 inches of its length near the middle is divided by light scratches or by centre-punch marks at intervals of an inch, from which the reduction in the area of the cross-section, and the amount of stretch under the pull of the load applied, is measured. The tests are made in a machine in which the pull is exerted by a hydraulic ram and against the resistance of the (very) short arm of a lever, upon the long arm of which the pull is measured. In the testing machine, the effect produced on the specimen by the gradually increased load varies greatly for different qualities of metal. Steel containing a large amount of carbon, of the quality generally used for the manufacture of springs, stretches slightly and uniformly up to the breaking point. In the case of softer steel, at the beginning as the load is gradually increased the metal stretches uniformly for a little while, but the period is much shorter than that of high carbon (harder) steel, then it stretches very rapidly for a few seconds, without any appreciable increase of the load, until it is apparently on the point of breaking, when it partially recovers its strength, and stretches slightly but uniformly as the load is gradually increased to the maximum. In the case of hard steel, the metal ruptures under the maximum load, but the soft steel continues to stretch for a little while beyond that point under a decreasing load, with a great reduction in the sectional area of the specimen. To determine the amount of elongation produced by the test, the fractured ends of the two pieces of the broken bar are put together and the increase in the lengths of the original inch spaces marked on the bar are measured. In very hard steel, the amount of elongation is very small, but even the hardest and most brittle varieties undergo a measurable change of length. In soft steel it is very great, varying from 25 to 30 per cent of the original length. The behavior of a specimen in the testing machine when subjected to a gradually increasing load is studied by means of a stress-strain diagram which consists of two sets of parallel lines intersecting each other at right angles. The horizontal lines represent the strains in pounds per square inch of the sectional area of the specimen, and the vertical lines represent the amount of elongation of the

specimen at the rate of 0.01 per inch of the original length. When the data obtained by the test are plotted upon the diagram, the behavior of the specimen is indicated by a characteristic curve. Assuming an original length of six inches (between the grips of the machine) for a specimen the behavior of soft steel under a gradually increasing load may be briefly summarized as follows: Up to a load of 40,000 pounds to the square inch the elongation is very slight, about 0.01 of an inch in a length of six inches. From 40,000 to 43,000 pounds the elongation is more rapid, but the total amount is only 0.02 of an inch. From this point the metal stretches very rapidly with no increase of load until the elongation amounts to 0.15 of an inch, then it apparently regains some of its strength and stretches slowly and uniformly until the elongation amounts to 1.96 inch, or 33 per cent of the original length, under a maximum load of 63,000 pounds to the square inch. An analysis of these results shows that it would require a load greater than 40,000 pounds per square inch to induce a permanent set in the metal, and is, therefore, the value representing its "elastic limit," or the limiting stress below which there is practically no change in the original length of the metal, no matter how often that stress may be applied or removed.

It is generally assumed that a constant proportion exists between stresses and strains. This relation is expressed by the term "limit of proportionality," and represents the limit below which each increase of a given amount in the load results in the same change in the length of the specimen. It agrees very closely with the elastic limit, but it is not considered an important factor in engineering calculations, while on the other hand the coefficient or modulus of elasticity, based upon the theory of the proportionality between stresses and strains, and obtained by dividing the stress on each unit of area of the section by the resultant strain in each unit of length, of a specimen, is extensively used in calculations pertaining to the deflection of beams and springs. The coefficient of elasticity for all grades of steel is practically the same, about 29,000,000, and very delicate measurements are required for its determination, so much so that the values obtained by different observers vary considerably, and places its exact value very much in doubt. For similar reasons, the determination of the exact value of the elastic limit of a metal is a very difficult matter, and as a rule the values stated as the elastic limit, in the reports of tests of specimens, sent out from rolling mills, is really the "yield point" of the metal, or the point at which the specimen suddenly elongates without any increase of the load, and although it is not theoretically as correct a gauge of the property of the metal as the true elastic limit, it is really a more reliable guide to the manufacturer and user, on account of the ease and accuracy with which it is determined by simple practical methods, and the fact that in good engineering practice structures are not intentionally designed to sustain a stress as high as the true elastic limit.

Relative to the ultimate or breaking strength of the metal, the tests show that the specimen continues to elongate under a decreasing load after the maximum load has been

applied, so that owing to the reduced sectional area the stress under which the specimen finally breaks is generally much less than the maximum, and represents the "tenacity," rather than the ultimate breaking strength of the metal. High elongation indicates a metal of good malleable and ductile quality, and if produced under a cold test shows that the metal is especially suitable for boiler plate, rivets, etc. Another element considered in the tensile test is the character and appearance of the fracture. It often takes a form described as "cup" or "half-cup," in which one of the ends is wholly or in part concave, while the other is correspondingly convex. In other cases, especially with flat bars, the fractured ends are quite flat and smooth, but with their surfaces making an angle of 45 degrees with the length of the bar, instead of a right angle, as in the case of the former. In hard steel the surfaces present a rough crystalline appearance, while in soft steel they have the glossy appearance of woven silk, or bundles of fine silk fibres. Although the character of the fracture is always noted in connection with the other data derived from the test, it is seldom made an important requirement in specifications owing to the impossibility of determining a fixed standard of comparison. Compression tests are made by the same machine in slightly different arrangement so that the hydraulic power is pressure instead of pull.

Cold bending tests are useful for the purpose of determining the ability of steel, or any other metal, to withstand severe distortion, when the metal is cold, under such operations as punching, shearing, flanging and riveting, usually employed in the manufacture of bridge members and structural shapes in general. The test does not require an expensive or elaborate plant for its application, and is, therefore, available where more complete tests are impracticable. On the other hand, however, it is very difficult to deduce accurate conclusions from the data obtained, owing to a lack of proper classification and standards of comparison. In making the test, the metal in each case is bent over upon itself through an angle of 180 degrees. The inner radius of the bend varies from 0, in steel with a tenacity less than 62,000 pounds per square inch, to the "thickness of the specimen" in steel with a tenacity not greater than 70,000 pounds per square inch. The specimen is required to stand the bending without fracturing on the outside of the bend. The test for hardness is applied by pressing or driving a hardened steel ball into the material so as to produce a dent. The diameter of the ball used is commonly 10 millimeters and the standard pressure used is 3,000 kilograms. The diameter of the indentation is then measured. Two indentations are usually made not far apart on the specimen being tested. The formula applied is

$$\frac{16 PD^2}{\pi(2d)^3} \times \frac{1}{1.0718}$$

this giving the hardness number in the Brinell scale. It has been objected to these ball tests that the tendency of the pressure is to raise up a cup-shaped rim of steel around the ball and above the level of the test specimen, and that the diameter measured will thus be of the raised cup. To obviate this a delicate instrument has been devised to measure the depth of the indentation below the level of the tested surface, and from this to

calculate the true diameter. Another method of applying this ball test is by a falling hammer which carries the ball upon its face. The standard weight of the hammer is 1.76 kilograms, and the drop may be any distance up to 90 centimeters. Several tests are made at different falls, and the results correlated. A variation of this test substitutes a cone-shaped point with an angle of 90 degrees for the spherical ball. This also is applied by a standard pressure or by the falling hammer, and a closer accuracy is claimed. As determined by these methods the Brinell hardness numbers for the commoner grades of steel are as follows:

Mild steel.....	120.
Boiler plate.....	128.
Rail steel.....	183.
High carbon steel.....	236.
Cast iron.....	213.

Another method of testing steel of great accuracy in the hands of an expert is the "spark test." This is applied by pressing the sample of steel for an instant firmly against a sharp emery wheel revolving 7,000 feet per minute. To the educated eye the kind of sparks emitted indicate with great certainty not only the proportion of carbon in the sample, but the several alloys with tungsten, manganese or chromium.

Other tests are made for endurance of steel samples, especially that used in the automobile industry. Such steels are tested for fatigue, being subjected again and again times without number to the same kind of strain, and also to shocks which they must safely withstand in the ordinary use of a car. These tests are applied by automatic machines acting unceasingly for many hours. Another test of great importance in automobile steel is the abrasion test for wear.

In some cases torsional and shearing tests are made, but these stresses are not commonly expected. The impact test is more often employed, applied by means of a heavy, swinging pendulum, or by an oft-repeated drop of a weight upon a bar supported at the ends. The tests of finished steel are similar to those made in the mills during the process of manufacture, with the exception of the methods employed in the preparation of the test specimens. These are cut directly from the finished product in the form of rectangular pieces 10 inches in length, in the larger kinds of work, while small bars are generally tested full size. Consult Bullen, D. H., 'Steel and Its Heat Treatment' (New York 1918).

STEEL, THEORIES OF HARDENING.

That steel has the property of hardening when suddenly cooled from a bright cherry heat has been known for centuries. The origin of steel hardening cannot be traced definitely, but Homer refers to it and Pliny, the Younger, describes a method which, in its main points, is general practice to-day. (Otto Vogel in *Stahl und Eisen*, 1899, p. 242). During the 15th and 16th centuries the practice grew to be an art and great secrecy and superstition were attached to it. Quaint and curious methods were evolved and the secret was hoarded and handed from generation to generation. Even to this day, in some sections, the same old type superstition exists among some of our own blacksmiths, and it is quite common to meet

with one whose ideas and practices are identical with those followed in the Middle Ages.

Many of the mechanisms of what happens during the process known as hardening have been studied and are known, but the real reason of why steel hardens is still in doubt. The very fact that there are at least seven distinct theories, in vogue to-day advanced by as many eminent metallurgists, is mute evidence of the fact that we are in the dark regarding this reason. Sir Robert Hadfield (Farady Society, November 1914) in discussing these theories says: "I cannot say that there is one which throws light on what really happens when a piece of carbon steel is changed from a soft to a hard condition." Dr. J. E. Stead (Farady Society, November 1914) expresses the opinion, "We have not sufficient data upon which to found any definite conclusion as to the process known as the hardening of steel by quenching," and Albert Sauveur (International Engineering Congress, September 1915, San Francisco), "It will likewise be obvious that no theory so far presented fully satisfies our craving for a scientifically acceptable explanation of the many phenomena involved." H. M. Howe (Farady Society, November 1914) says "Each of these theories has its difficulties," and Rosenhain ('Study of Physical Metallurgy,' p. 180) says regarding Martensite (the normal constituent found in normally hardened steels), "The question 'What is Martensite?' cannot be answered quite conclusively, particularly as several rival views are in the field."

In the usual practice followed in hardening a piece of ordinary carbon steel the operation is an extremely simple one. It consists of heating the piece to a predetermined temperature, holding at this temperature for a length of time sufficient for the entire mass to be evenly heated and then suddenly cooling it. The cooling is usually done by immersing in a liquid, usually water or oil.

The simplest steel has at least two constituents, one iron or ferrite, and the other a carbide of iron or cementite, and, in order to gain an inkling of what transpires, it is necessary to study the properties of these two constituents.

If we plot a cooling curve of pure iron, we find that at 898° C. and 768° C. marked evolutions of heat occur, indicative of a change in the physical properties (see Fig. 1), while, if carbon be present, as in steel, a third evolution of heat occurs at 690° C. (see Fig. 2).

Floris Osmond (*Journal Iron and Steel Institute*, No. 3, 1906, p. 444), in a series of brilliant researches first brought out the momentous discovery that iron exists in three separate and distinct allotropic modifications. At all temperatures up to 768° C. pure iron or ferrite exists in the Alpha condition. Between this temperature and 818° C. it is in the Beta condition, and above 898° C. it exists in the Gamma condition. In each of these three conditions the physical properties are entirely distinct. Crystallographically, they are all of the cubic system, but the Gamma iron assumes the octahedra while the Beta and Alpha assume the cube. Twin crystals are frequent in the Gamma, but the Beta and Alpha are free from them. Alpha iron is magnetic, and the change from Alpha to Beta is accompanied by an abrupt change in the electrical conductivity, strength and hardness and crystalline form. On cooling,

changes occur which are the reverse of, and appear at very nearly the same temperatures as, those on heating. The points on heating are known as the AC_1 and the AC_3 ; on cooling, as the AR_1 and the AR_3 . When carbon is present, a third evolution on cooling takes place at about 700°C . which is known as the AR_2 and the reverse as the AC_2 . The ranges in which these changes occur are known as the critical ranges.

The carbon in steel exists in the form of a definite chemical compound known as cementite which has the chemical formula Fe_3C . It crystallizes usually in flat plates or needles which in some cases coalesce into the form of granules. It is the hardest constituent of steel and is attacked by ordinary reagents less than the other constituents.

FIG. 1.—Inverse Rate Heating and Cooling Curves of Pure Iron. (Burgess and Crowe, Transactions American Institute Mining Engineers, XLVI, 1913).

Cementite and ferrite are the two most important constituents of steel, and it is, therefore, their inter-relation which we must study in order to understand what is transpiring, constantly bearing in mind that the ferrite can and does exist in three different allotropic conditions depending upon the temperature. At ordinary temperatures cementite and ferrite exist together as completely decomposed constituents, and, in the lamellar condition, arrange themselves in tiny flakelets. Upon heating to the Gamma range of temperatures, cementite dissolves in the Gamma iron with the result that there is formed a constituent known as austenite. In only special cases can this be preserved at ordinary temperatures because it is extremely unstable and breaks down into martensite, this latter being the usual constituent found in ordinary hardened steel.

There are two sharply defined schools attempting to explain the problem of hardening, and below is given classification in tabular form.

(Sauveur, 'The Metallurgy and Heat Treatment of Steel,' p. 308).

I. RETENTION THEORIES	A. Solution theories	a. Beta iron or allotropic theory. Osmond.
		b. Alpha iron theory. H. LeChatelier.
	B. Amorphous iron theory, Humphrey.	
II. STRESS THEORIES	C. Carbon theories	a. Hardening carbon theory.
		b. Sub carbide theory, Arnold.
	A. Early stress theory, Andre LeChatelier.	
	B. Interstrain theory, McCance.	
	C. Twinning and amorphous iron theory. Carpenter and Edwards.	

I. *The Retention Theories* base their ideas on the claim that a condition or set of conditions existing normally above the critical range

FIG. 2.—Inverse Rate Heating and Cooling Curves of Mild Steel. (.106 Carbon) (Rosenhain and Humphrey, Journal of the Iron and Steel Institute, LXXXVII, p. 232).

are, by sudden cooling, retained as such or a transformation therefrom, which state is unstable and, upon tempering or reheating, tends to revert to the original or normal condition.

IA. *The Solution Theories* claim that the constituents or a part of the constituents existing normally at ordinary temperatures, on heating, pass into a solid solution and are retained in this state upon sudden cooling. The idea of one solid dissolving another solid may be new to some readers but under certain conditions this is true. As an example, gold and silver are mutually soluble in each other in all proportions.

IAa. *The Allotropic Theory* claims that the hardness of steel is due to the presence of Beta iron. The followers of this theory believe that, on heating, the cementite dissolves in the Gamma iron and, on sudden cooling, the Gamma iron immediately breaks down, forming a certain amount of Alpha iron but mostly Beta iron which still retains the cementite in solu-

tion. They believe that the cementite in solution simply (as Howe puts it) acts as a brake on the Beta iron and prevents it from entirely reverting to the Alpha iron. Were it possible to obtain Beta iron by means other than the solution of the cementite, the material would still be hard. The allotropists are also of the opinion that, in the transformation from the Gamma to the Beta, the internal pressure may contribute to the final hardness.

IAb. *The Alpha Iron Theory* denies the presence of Beta iron entirely, and explains that the hardness is due to the fact that, on cooling, the Gamma iron with the cementite in solution changes directly to the Alpha form, which latter still retains the cementite in solution. This theory has little or no standing, since the careful and thorough experiments of Dr. G. K. Burgess (Bureau of Standards, Scientific Paper, 1914) have proved conclusively the presence of Beta.

IB. *The Amorphous Iron Theory* was brought out by J. C. W. Humphrey and seconded by Rosenhain (Rosenhain, 'Study of Physical Metallurgy,' p. 181). The followers of this theory believe that the hardness of steel is due to the presence of an intrinsically hard but unstable product, amorphous iron. "The Gamma iron crystals, in passing through the transition temperature, break up, leaving the molecules temporarily in a chaotic (amorphous) condition pending their reorganization into crystals of Alpha iron and cementite, and it is only this rearrangement which is stopped by the rapidity of cooling." Rosenhain believes further that the breakdown of the Gamma crystals occurs only around the boundaries of the growing crystals of Alpha iron.

IC. *The Carbon Theories* claim that the hardness is due to the retention in the cold of a very hard form of carbon.

ICa. *The Hardening Carbon Theory* claimed that the hardness of steel was due to the presence of hardening carbon, which was stable only above the critical range. This theory is now pretty much discredited.

ICb. *The Sub-Carbide Theory*.—Arnold believes in the existence of a carbide Fe_3C , which he has named hardenite, and that it is due to the retention of this constituent that steel owes its hardness. He establishes the identity of this carbide by an indirect method and the theory has little support to-day.

IIA. *The Early Stress Theory*.—When steel is heated to its critical range it expands at a rate which is approximately directly proportional to the temperature change. On passing through the range it contracts. Then, on heating above the range, it again expands, but at a rate greater than it did before. (LeChatelier, 'Contribution to l'Etude des Alliages,' p. 386). On cooling, the reverse occurs and the stress theories attempt to explain the hardening as being due to the immense strains set up thereupon.

IIB. *The Interstrain Theory*.—McCance says (*Journal of the Iron and Steel Institute*, 1914, No. 1, p. 233): "On quenching steel the carbon is retained in solution and, in turn, it retains a portion of the iron in the Gamma condition, but the majority of the iron is Alpha iron. At the quenching temperature, the crystalline grains had the crystalline symmetry of Gamma iron, and the Gamma iron retained in the

quenched state by the carbon will form an internal network in these original steel grains. The units of the iron will be transformed and will form crystal units of Alpha symmetry, but these will be prevented by lack of time, by internal friction and by the Gamma iron network from arranging themselves to form homogeneously orientated Alpha iron crystals. The Alpha iron will thus be in a condition similar to interstrain and great hardness will result."

IIC. *The Twinning and Amorphous Iron Theory*.—Professor Carpenter and Edwards advance the theory that "In the operation of quenching, the normal heat of the carbide or other similar change is retained in the rapidly cooled material and, when the change is suppressed in this way, severe internal stresses are set up and these cause internal straining of the material." That this is a fact is proved because the "Metallic crystals are broken up into an exceedingly large number of twin lamellae."

There is a further type of hardness which is common to metals including steels which is different in many respects from the hardness produced by sudden cooling. This is the well-known hardening effect of cold working, such as hammering, swedging or cold drawing.

STEEL CAR INDUSTRY, The. The building of steel railroad cars is recognized as one of the most prominent of our industries. European countries were pioneers in the use of iron cars, and as early as 1861 we find records of cars with iron bodies being built in France, while in India, iron was substituted for wood at an early date, as the latter material was particularly susceptible to the attacks of ants and other insects, which condition necessitated the use of iron or steel in the construction of equipment for use on the railroads of that country. In other foreign countries the selection of iron for this purpose was undoubtedly governed largely by the comparative cost of iron and wood, which in many instances favored the use of the former material, and also for the reason that climatic conditions in many of these countries are such that wooden cars rapidly disintegrated. To the American engineer, however, should be given the credit of foreseeing the possibilities of steel in car construction, not solely from a constructive standpoint, but as a scientific solution of the problem of economical transportation. The successful operation of a railway is dependent on the relative cost of transportation, and the use of steel in car construction has made it possible to decrease to the minimum the percentage of dead weight to that of paying load. The progress made in the proper appreciation of the stresses to which the different parts of a car are subjected has resulted in great improvements, providing ample strength for the duties imposed on the several parts, eliminating superfluous material where it may be done without detriment to the car as a

whole, thus producing, in steel, cars of minimum weight and maximum strength. This favorable comparison of percentage of dead weight to paying load is much more evident in the higher capacity cars, where the full benefit of the difference in strength between wood and metal may be realized.

The capacity of freight cars in this country has been continually on the increase, and constant efforts are being made to reduce the relative proportion between weight of car and weight of lading. Up to 1876 the average freight car had a carrying capacity of 20,000 pounds, while the ratio of paying load to total weight of car and lading was about 47 per cent. In 1880 the capacity had been increased to 40,000 pounds, and the ratio of paying load to 60 per cent; in 1883 to 50,000 pounds and 65 per cent; in 1889 to 60,000 pounds and 66 per cent; in 1895 to 80,000 pounds and 68 per cent; and in 1903 to 100,000 to 110,000 pounds and 75 to 79 per cent, respectively.

In the catalogue of all-steel cars manufactured in 1918, the largest load capacity is that of the 120-ton gondola car. It is 50 feet in length, 9 feet 8 inches in width and with walls 7 feet 4 inches high above the floor level. This car weighs about 74,000 pounds and with its full load represents a total weight of 314,000 pounds—the paying load approximately 77 per cent. The standard all-steel 50-ton box (freight) car varies in weight from 43,100 pounds to 52,600 pounds. It ranges in inside length from 36 feet to 40 feet; from 8 feet 6 inches to 9 feet in inside width, and from 8 feet 4 inches to 9 feet 2 inches in inside height. The higher weight car carries a paying load of 70 per cent of the total weight; the heavier car a paying load of about 66 per cent. Hopper cars for coal carry 100 tons upon a car weight of 60,000 pounds to 75,300 pounds, the paying load thus ranging from 77 to 73 per cent of the total rolling weight. The 100-ton flat car and the 110-ton well-hole car, weighing respectively 90,000 pounds and 92,000 pounds, have still lower paying efficiency. However, when durability is considered, the heavy cars are more economical in the long run, and with their far greater burden serve to roll up the record of ton-miles with far greater rapidity than the light car of smaller burden. The modern all-steel passenger coaches range in weight from 116,000 to 146,000 pounds, and the dining-cars, the heaviest of all standard coaches, reach 175,000 pounds.

The general introduction of the steel car was not accomplished without serious opposition; first, from those who were directly interested in the manufacture of wooden cars; and second, from those who were skeptical as to the advisability of adopting steel as a vehicle of transportation, exposed to the action of injurious elements which might cause a rapid deterioration of the metal and a consequent reduction in strength. However, up to the present time no serious effects from this cause can be noticed in the cars now in service. If proper attention is given to the method of construction and weight of metal used, and all parts are thoroughly painted at the time of manufacture to protect them from corrosion, and if after the cars are placed in service care is taken to repaint them when necessary, it is

fair to presume, judging from the present condition of the earlier steel cars built in this country, that we may reasonably expect an average length of service from the steel car of at least 30 years, or fully twice as long as the service obtained from cars of wood construction.

The steel car industry may be correctly said to date its origin in this country from the year 1896, although the records of the Patent Office show that patents were granted to citizens of this country, as well as of foreign countries, for cars made entirely of steel or other metal, as early as 1854, and it is also true that prior to this time cars of metal, or a combination of metal and wood, had been constructed and put in service in this country; but these early efforts had little in common with the modern steel car, now standard on many of our leading railways. Previous to the year 1897 many cars had been constructed in this country of steel or iron, but were built for special service by the several railroads, mainly for the purpose of facilitating the transportation of heavy materials, where the load was more or less concentrated, such as wire cables, guns, bridge girders, etc. In the design of such special equipment no particular attention was given to the consideration of a reduction of the weight of the component parts, with the result that most of these earlier metal cars were excessively heavy and not suitable for general service.

Iron-box cars were used as early as 1862, these having been built by the Baltimore and Ohio Railroad and weighed 18,000 pounds, with a capacity of 30,000 pounds. Later, in 1869, the Lake Shore and Michigan Southern Railroad placed in service flat cars with iron channel sills, and the New York Central and Hudson River Railroad had several metal cars running on its road as early as 1873. In these cars the substitution of iron for wood was more particularly confined to the underframing of the car, the superstructure, if any, being of wood. In connection with these early types of metal underframes mention may also be made of steel underframes for carrying water tanks of locomotives, which were in use as early as 1881.

It was not until 1887, however, that metal underframe cars were placed in service in any considerable numbers, these being built under patents owned by the Southern Iron Car Company, who constructed several thousand steel-underframe freight cars, including box cars, hopper bottom gondola cars, flat cars, etc. These underframes were of the iron tubular type, being formed by the assemblage of different sizes of wrought-iron pipe, tied together by means of threaded connections, so as to form a light and compact structure. However, in actual service it was found that the connections would rapidly loosen, thus destroying the strength of the whole, and after only a comparatively short time the construction of cars of this type was entirely abandoned. From this time on numerous experimental cars with steel underframing were built, but the unsatisfactory results derived from the tubular underframe undoubtedly retarded the adoption of the modern type of steel underframe car. The Pennsylvania Railroad in 1887 built a number of cars having steel underframes which were designed to carry a concentrated load of 120,000

pounds, and a steel fireproof car was built in 1889 at the shops of the Louisville, New Albany and Chicago Railroad. The Chicago, Burlington and Quincy Railroad, about the year 1890, placed in service a steel car of 60,000 pounds capacity, constructed from designs of the Harvey Steel Car Company.

In 1894 the Carnegie Steel Company ordered from the Fox Solid Pressed Steel Equipment Company, of Joliet, Ill., a number of steel-flat cars of 80,000 pounds capacity, to be used in service about its mills for the transportation of heavy billets. These were built entirely from pressed steel shapes and embodied in their design special features of pressed-steel work, being similar in this respect to cars then being built by the Leeds Forge Company of England, both the Fox Solid Pressed Steel Equipment Company and the Leeds Forge Company being controlled by Sampson Fox, who was the originator of pressed-steel shapes in car construction. Up to this time, 1894, the possibilities of the use of steel in car construction, it is fair to state, were not fully appreciated by those controlling the design and operation of railroad equipment, and to the Carnegie Steel Company should be given the credit for properly placing before the railroad world the possible advantages to be derived from the use of an all-steel car. The interest displayed by the Carnegie Company was no doubt largely the result of a desire to increase the demand for its product by providing additional avenues for the consumption of steel plates and shapes. The arguments at the time set forth in favor of the use of steel for freight-car construction, and all which claims experience has since verified, were lightness, durability, strength, greater proportion of paying load to total weight of car, reduced cost of maintenance, less liability to damage and greater salvage value.

To further exploit the possibilities of steel in car construction the Carnegie Steel Company in 1896 had built at the Keystone Bridge Works three all-steel cars, one of these being a steel-flat car and two self-clearing hopper cars, in which the floors are inclined from the ends downward toward the centre and at the bottom of these inclines doors being provided, which, when opened, permit the load to discharge by gravity. These cars were exhibited at the conventions of the Master Car Builders and Master Mechanics' associations, held at Saratoga in June 1896, and elicited the interest of car builders and railroad men throughout the country. Rolled plates and shapes, which could be purchased in the open market and all of which constituted the product of the Carnegie mills, were used in the construction of these cars.

Previous to this time the Schoen Pressed Steel Company, of Pittsburgh, Pa., had for a number of years been manufacturing various parts of cars by pressing plates into special shapes. This company was the first to introduce a design of an all-steel self-clearing hopper bottom coal car built entirely from pressed shapes, these being built under patents issued to C. T. Schoen and J. M. Hansen. The prompt and extended adoption of the all-steel car is undoubtedly due to the aggressive policy pursued by this company and its successor in the introduction of its product. The designs for

these cars were placed before railroad engineers shortly after the exhibit of the cars built at the Keystone Bridge Works for the Carnegie Steel Company. The Carnegie Steel Company, owning and operating the Pittsburgh, Bessemer and Lake Erie Railroad, extending from Pittsburgh to Lake Erie, decided to place in service on this road enough cars to thoroughly demonstrate the possibilities of cars built of steel, and early in 1897 placed with the Schoen Pressed Steel Company an order for 600 self-clearing steel hopper cars of 100,000 pounds capacity, it being specified that 400 of these cars were to be of the structural design originally prepared by the Carnegie Company's engineers, and 200 to be of the pressed steel design advocated by C. T. Schoen. At the time of the placing of this order, it may be interesting to note that there was no industrial establishment in the country specially equipped for the construction of steel cars and the Schoen Pressed Steel Company was not able to turn out one complete car per day. Upon being awarded this order, however, those interested in the Schoen Pressed Steel Company, of which C. T. Schoen was the executive head, immediately arranged for the extension of its plant and carried on the work of enlargement simultaneously with the construction of the cars, with the result that the entire order for 600 cars were completed in nine months, the first car having been completed in June 1897.

Following the order of cars for the Pittsburgh, Bessemer and Lake Erie Railroad, the Pittsburgh and Western Railroad placed with the Schoen Pressed Steel Company an order for 450 pressed steel self-clearing hopper cars of 100,000 pounds capacity. These two orders marked an epoch in car construction and railway freight transportation and the steel car industry was firmly established, and has since grown with phenomenal rapidity. As already stated, the cars for the Pittsburgh, Bessemer and Lake Erie Railroad were of two different designs, one employing rolled sections and the other pressed shapes. As both were along radically different lines from previous designs of either wood or metal cars a general description of both types may prove of interest.

The cars designed by the Carnegie Steel Company were what is known as the hopper bottom type of car, the cubical capacity being about 1,400 cubic feet. The centre sills consisted of two 15-inch I beams, and the side sills were 12-inch channels with their flanges placed inward. No intermediate sills were used. The plates forming the sides of the car extended to the bottom of the side sill channels, and were riveted to the web of same. This latter form of construction was employed on the first sample car, but on later cars was modified by omitting the channel side sills and riveting an angle along the lower edge of the side plates, a second angle being riveted to the plates about 18 inches higher up, both angles extending the full length of the car. The body bolster was of a built-up latticed girder type, and the floor of the car was made up of inclined steel plates and a cross-hood placed at the centre of the car. This car weighed about 37,150 pounds. The car made of pressed steel was similar in general appearance to the above described car, but differed materially in the details of con-

struction. The centre sills were made of plate, pressed to channel form, being 17 inches deep at the centre and tapering to 10 inches deep at the bolsters. The side sills were of similar construction, and the side plates were flanged at both top and bottom, the bottom flanges being riveted to the top flanges of the side sills. The body bolsters also were of pressed steel, being trough-shaped in form. This car weighed about 34,350 pounds.

At about the time the order for the Pittsburgh, Bessemer and Lake Erie cars was placed the Pittsburgh and Lake Erie Railroad was designing a hopper car along somewhat similar lines to the cars designed by the Carnegie Steel Company, and a sample car in accordance with these designs was built by the Youngstown Bridge Company, this car being completed and placed in service about March of 1897. In this car the centre sills consisted of 15-inch I beams, the sides of the car being built-up plate girders, with diagonal reinforcing angles extending from top to bottom and stiffening angles extending the length of the sides being riveted to the upper and lower edges, thus forming a girder which was designed to carry the entire load. In order to reduce the weight of the car the side sheets below the floor line, from the bolsters to the ends of the car, were cut out. This car was of 100,000 pounds capacity and weighed 35,500 pounds. No pressed shapes whatsoever were used in its construction.

Up to this time all the cars built by the Schoen Pressed Steel Company were of the hopper bottom type, but the value of steel in freight car construction having been fully demonstrated, orders for other types followed in rapid succession, so that to-day practically all forms of freight cars, including hoppers, flat bottom gondolas, flat and ballast cars, have been constructed from steel in large numbers.

The adoption of the idea of maximum train loads, and the consequent enormous increase in the tractive power of the locomotive, served to further increase the popularity of the steel car, as it early became evident that the draft rigging and underframe construction of the wooden car would prove inadequate for the severe service to which they were subjected. As a consequence many cars of the box, stock and gondola types were built with steel underframing and having a superstructure of wood as a substitute for the original all wood structure. Cars of this type have given very satisfactory results in service, as with the combination all the desirable features of the wooden body are retained, while the underframe is sufficiently strong to resist the most severe buffing and pulling strains. A further advance in the substitution of steel in cars of the combination type has recently been made by the use of steel posts, braces, plates and carlines as a substitute for those of wood, thus producing a complete steel frame car.

The successful results obtained from the introduction of rolled steel as the basic material in many large engineering enterprises warranted its careful consideration in the infancy of steel car construction, and when the Carnegie Steel Company specified that the major portion of its first order for steel cars was to be constructed of rolled section, it is evident that from the very beginning it was

recognized that the ideal car would be one made throughout of standard commercial shapes. As pressed steel, however, admitted of the production of shapes of the exact form desired, and the early development of the steel car being in the hands of those predisposed in favor, and interested in the manufacture, of pressed steel parts, it is natural that great progress was first made in the perfecting of this latter type of construction, while the car made of rolled sections remained for the time in its original crude state, being clumsy and heavy when compared with the more highly developed pressed steel car. The advantages of constructing a car from a few standard commercial shapes, easily obtained in the open market, especially when considering the question of repairs, rather than from numerous special parts, requiring expensive machinery in their manufacture, were too manifest, however, to permit of being long ignored, and that it was possible to build cars from standard rolled sections, having all the advantages of light weight and maximum strength claimed for the pressed steel car, has been fully demonstrated by the later developments of the art, and is amply evidenced by the numerous structural steel cars now in service which compare favorably with the pressed steel types in the matters of lightness, strength and simplicity of construction.

With the increasing demand for the steel car it is natural that a very inviting field for the investment of capital was disclosed, with the result that we have to-day in the United States a score of large corporations actively engaged in this line of manufacture. The Pennsylvania Railroad builds its own steel cars, both passenger and freight designs; and several other railroads build freight cars for their own use. Besides the very large domestic trade the steel car builders have developed a profitable and growing export trade which is destined to be much larger in the near future, as the Belgium production, heretofore the chief competition in the foreign markets, must necessarily be small for several years to come.

STEEL TUBING. This is the most modern and one of the widest used products of steel. For many years steel tubing was not considered entirely satisfactory by manufacturers because the welded parts were not as strong as the rest of the tubing. This difficulty has been overcome and to-day steel tubing finds a remarkable market in the manufacturing of automobiles, engines, furniture, baby carriages, beds,

boilers, etc. Steel tubing is made from solid or hollow billets or from steel ribbon.

Technology.—There are four methods of manufacturing steel tubing, i.e., lap welding, butt welding, the piercing method and the Lloyd oxy-acetylene method. The lap method has been in vogue for many years, dating back to the period when steel first began to be used. The early manner of lap welding was known as spiral welding. Steel sheets of a desired width were wound spirally to form a tube. The spiral joints were heated and welded by a hammer, although in many cases these joints were cold riveted. An even earlier method of making steel piping was to take two semi-circular pieces of steel and insert the edges into steel bars with grooves in either side. These were held in place by pressure applied on all sides. There was no welding or joining of the semi-circular pieces and the piping thus made was useless except for underground purposes or in such places where the pressure could be applied at all times. Later came the straight lap welding, where flat steel of a desired width was passed through rolls, drawn over dies and formed with the edges overlapping. Heat was applied and the overlapping edges were hammered or squeezed together. This left the welded part thicker and stronger than the rest of the tube and was never satisfactory for good manufacturing work. In a later method—the flat steel ribbon was heated and the edges were scarfed or bevelled by passing through rolls, drawn through dies and so formed that the scarfed or bevelled edges of the one side of the flat steel fitted into the same edges of the other side. This partly-made tubing was then reheated, passed through rolls with the inner lap resting on a stationary mandrel. The rolls and the mandrel pressed the heated steel together and welded it. The rough tubing was then passed through sizing rolls, straightened, rolled on cooling tables and finally forced through straightening machines by hydraulic pressure. Butt welding then came into use, the first process requiring that the entire piece of flat steel be heated to a welding heat and drawn through a conical shaped die, so that square edges were pressed together. Then came the brazing process of butt welding, in which a blow-torch like that of a tinsmith, only with far greater heat, was used to centralize the heat at the square edges where the brazing is to take place. The brazing method is used when very thin tubing is to be made because the heat of the blow-torch is not sufficient to make thicker steel tubing. It is largely used in brass or copper welding, where a heat of from 1,200° to 1,400° is required, while steel needs from two and one-half to several times that heat. The electric process consisted of heating the edges and applying pressure so that the steel is pushed together and welded at the same time. Flat steel is put through conical shaped rollers, bringing the edges of the steel together at the point where electric heat is applied. As the steel is heated the rollers press the edges closer together. This was a decided improvement over other processes of butt welding, but the greater strength and thickness of the welded part made several other processes of rolling, etc., necessary before the tubing was ideal.

The piercing seamless method is the latest and most efficient for producing heavy steel tubing. Solid or hollow billets are heated to about 2,300° and passed through diagonal rolls traveling at a tremendous speed. These rolls work the steel into desired size. While the billet is passing over the rolls it is pushed against a mandrel which is stationary but revolving 2,400 times per minute. The billet is thus worked into a desired size with a hole through the centre and comes through a tube after many operations. For example, if a two-inch tubing 46 inches long is desired, a billet three inches round and 26 inches long is heated, passed through the diagonal rolls and at the same time has the mandrel passed through it. When this operation is completed the tubing measures three and one-half inches on the outside with a seven-sixteenths shell. It is then taken to the round rolls where it is elongated and the shell reduced. Then it is cold drawn, hot rolled, pickled, cold drawn, annealed and so on. The lighter the shell desired the more operations necessary. The piercing method found itself very applicable to the hollow steel billet made first in Sweden, where the molten steel was poured over a core, the latter removed when the steel shell had cooled, thus leaving a round billet with a rough hole through the centre. This made it possible for the piercing method to become much speedier in production.

The Lloyd oxy-acetylene is the latest method of producing thin gauge steel tubing. Until this method was invented thin-gauge tubing was exceedingly costly in comparison to larger gauge tubing, owing to the many more treatments required in order to get a thin-walled tube. The Lloyd oxy-acetylene method requires steel ribbons of desired widths. The ribbons are passed through oval-shaped rollers, thus bringing the square edges close together. The partially shaped tubing then passes to other rollers which press the edges very close together. At this point oxy-acetylene heat is applied at about 2,500° and the welding takes place. It is then polished, cut off to desired lengths and comes out of the machine ready for use. A single machine accomplishes the entire work. The Lloyd oxy-acetylene method differs from the butt welding in that the steel edges are not pressed together and only a very small portion of the partially shaped tubing is heated. So delicate is the operation that a seamless tube is produced in desired lengths without waste.

History.—While the use of iron and steel has become so common in mechanical and structural work as a result of modern ingenuity, it is hard to realize that nearly five and one-half centuries passed by after the discovery of iron before steel became a commercial product. Iron was first found, say historians, in the pyramid of Gizeh, where it had been placed by builders, most likely as a relic. This same iron to-day rests in the British Museum. So far as is known iron was used commercially for the first time by Assyrians in Egypt. They made various kinds of tools, etc. History shows that for some time before the coming of Christ iron was used in making the implements of war, tools and other articles. It was not until 1350, however, that cast iron

STEEL TUBE WELDING

1 The Lloyd Oxy-Acetylene Steel Tube Welding Method and Machine, the only machine in the world that takes flat ribbon steel, rolls it into a tube, welds it, polishes it and cuts it off to proper lengths ready for use. Note ribbon steel passing into rollers in front of photograph

2 The Lloyd Endless Vise, showing how endless tubing can be carried through it to the welding torch, the latter being shown with its nose between the two endless vise wheels

and steel first made their appearance, when a German metallurgist produced them. The inventions of the Bessemer process for manufacturing steel opened this metal up to commercial use. This took place in 1855. The use of steel became an important product in mechanical and manufacturing history very soon after processes for preparing it were invented. The first known use of steel as a tube or pipe is the Coolgardie pipe-line, 328 miles long and 30 inches in diameter. This pipe was not welded. It was formed by taking ribbon steel and bending into semi-circular shape. The edges were inserted into steel bars with grooves on either side. Heavy pressure was applied on the plates and bars, thus rendering the pipe serviceable. Steel tubing itself was one of the very latest uses of steel owing to the early inability to make welded steel tubing so that the welded portion was of the same strength as the rest of the tube. Later, just the opposite condition arose, but to-day the piercing and Lloyd oxy-acetylene methods have overcome all these objections. The early lap and butt welding methods were not satisfactory for high-class work, and it was not until Mannesman Brothers, German by birth, but residents of Landore, Wales, and backed by British financiers, brought out the piercing method. They took round or square steel billets and pierced and rolled them to the size desired. This was a seamless method in which no welding was required and, therefore, gave great impetus to steel tubing uses. Improvements on the Mannesman method have been made by W. C. McCool of Beaver Falls, Pa., he being the first to invent a cold draw bench for drawing cold shafting. R. C. Steifel made other improvements at Ellwood City, Pa. He followed these with new improvements at Shelby, Pa., while George J. Thust added more at Detroit and Milwaukee, where mills were built in which the piercing method was used. The great difficulty of the piercing method arose when thin-gauge tubing was required, for the thinner the gauge the more rolling and drawing required. These many operations made the cost of thin-gauge tubing almost prohibitive. It was not until 1910 that Marshall B. Lloyd of Menominee, Mich., solved the problem of the thin-gauge, seamless steel tubing. High prices, long delays and imperfect thin-gauge tubing drove Mr. Lloyd into inventing the Lloyd oxy-acetylene method of making seamless steel tubing. By this method the very thinnest gauge steel tubing is possible, the thinner the tubing the cheaper the price, due to the fact that under the Lloyd method the real cost of the tubing is the material, while in all other cases the high cost is due to the numerous operations in which labor plays an important part along with material.

GEORGE W. ROWELL, JR.

STEEL WIRE AND NAIL MAKING.

The importance of the steel wire and nail industry in the United States may be measured by the fact that in 1902 there was produced a total of 1,574,293 tons of wire rods of which nearly 500,000 tons were made into wire nails. In 1909 the production of wire rods was 2,514,504 tons, valued at \$67,440,000. The 1918 output is estimated as 3,000,000 tons, of the value of \$100,000,000. About one-fourth of this goes

into nails. Time was when both wire and nails were manufactured entirely from wrought iron, and to secure the toughness and high tensile strength required, great care had to be used in the preparation of the iron, the cost of the product being proportionately high. It was only a question of time before steel, because of its less cost and its high strength, became the standard material in this as in other branches of the iron and steel industry; and today practically the whole of the wire and wire nails used are made from either Bessemer or open-hearth steel, the latter being specified where wire of the special grades with higher physical properties is required.

Physical Properties of Steel Wire.—As showing the great increase in strength of steel over iron wire, it may be mentioned that while good black iron wire will show an ultimate tensile strength of about 25 tons to the square inch, and bright hard-drawn wire a strength of 35 tons to the square inch, Bessemer steel wire will stand a strain of 40 tons and open-hearth steel wire 60 tons to the inch. Of the "special" grades of wire a high-carbon open-hearth steel will stand about 80 tons, crucible cast-steel wire about 100 tons, and the best cast steel, or as it is sometimes called, "plow" steel wire, 120 tons to the square inch; while certain qualities of cast-steel wire, made under specifications calling for a particular composition and requiring very elaborate working, have been produced, showing an ultimate breaking strength of from 150 to 170 tons to the square inch. The process of wire-drawing serves greatly to improve the physical qualities, and the smaller the size to which the wire is drawn down the greater is the ultimate breaking strength. The wonderful qualities of piano wire are proverbial, the average strength of English piano wire as given by the manufacturers ranging from 225 pounds for No. 12 music wire gauge, which is 0.029 inch in diameter, to 650 pounds breaking strength for No. 22, which is 0.052 inch in diameter. Reduced to the square-inch unit, the ultimate tensile strength per square inch would range from 300,000 pounds to 340,000 pounds. The composition of this remarkable wire is as follows: Carbon, 0.570; silicon, 0.090; sulphur, 0.011; phosphorus, 0.018; manganese, 0.425. An analysis of another wire of unusual strength known as "plow," shows 0.828 per cent of carbon, 0.587 per cent of manganese, 0.143 per cent of silicon, 0.009 per cent of sulphur, 0.030 per cent of copper and no phosphorus. The tests of this wire ran from 200,000 pounds per square inch for wire 0.191 inch in diameter to 350,000 pounds for wire 0.093 inch in diameter. Of course, with such high tensile strength the elongation or stretch was very small, ranging from 0.75 to 1.1 per cent only.

Billet Yard.—The bulk of the wire and wire nails of commerce are manufactured from Bessemer billets. Open-hearth billets are worked up into rods for the manufacture of chain, for special grades of wire and for various finished products in which high tensile strength is called for. In each rod mill billet continuous-heating furnaces are continually at work. The billets, which are 4 × 4 inches in section and 36 inches in length, are fed transversely into the furnace, side by side. They are pushed through the furnace door by a hydraulic charging machine, and by the time they have been heated to the proper

temperature for rolling, they are pushed, one after the other, out through the rear door of the furnace and fall upon a conveyor, by which they are carried down into the rod mill.

Roughing Mill.—The roughing mill consists usually of eight pairs of rolls, in which the billet is reduced from a 4-inch x 4-inch section to a three-fourths inch square section, and it is in this mill that the steel receives the first instalment of that thorough mechanical working which contributes so greatly to its ultimate tensile strength. Each pair of rolls is placed at an increasing distance from the one that precedes it, in order to allow for the increase in length due to the decrease of section of the billet. It has been found, moreover, that by changing the shapes of the grooves in the successive pairs of rolls, making them alternately square and oval, oval and round, etc., there is not only an economy of power secured, but a more thorough working or manipulation of the metal is obtained, and its qualities are proportionately improved. In the eighth set of rolls, or "pass," as it is technically known, the grooves are three-quarters of an inch square. From these, the last pair of roughing rolls, the rods are carried to the finishing mill.

Finishing Mill.—In this mill the wire rods are given commonly 10 more passes and brought down to the required dimensions. The finishing mill generally lies at right angles to the roughing mill; and instead of the rods passing through pair after pair of rolls in a continuous straight line, they pass through the successive rolls in alternating directions, describing half-circles between each pair. In order to guide the rods into the proper rolls, workmen stand between each pair, and as the rod issues from the rolls it is seized with a pair of tongs, bent around through a half-circle and fed to the next "pass." Consequently, when a rod mill is in full blast, it presents one of the most interesting sights. Owing to the rapid decrease in section and increase in length, as the rod passes through the successive rolls, it is necessary that the speed of the successive rolls be increased; and by the time the rod issues from the tenth roll of the finishing mill, it is traveling at a speed of 1,350 feet per minute, or about 15 miles an hour. As the whole of the rolling down from the 4-inch x 4-inch billet to the finished rod, which will be, say, 13-64 of an inch in diameter, is done at one heat, it can be understood that the scene is extremely picturesque. In order to protect the men who stand between the pairs of rolls and direct the course of the rods, a series of curved semi-circular guards or shields are fastened upon the iron floor of the mill. The amount of working to which the steel is subjected, and the great horse power that is required to perform this duty, may be judged from the fact that the billet, which at the first pass through the mills was 4 inches x 4 inches in section and only 3 feet long, as it issues from the last pair of rolls is a scant quarter of an inch in diameter and measures no less than 1,189 feet, or not far from a quarter of a mile in length. As the rods leave the last pair of rolls the ends are caught up and attached to the drums of a set of reels, on which they are wound up into a convenient coil for further handling. As soon as the coil is completed, it is dropped from the

reel onto the floor of a conveyor, by which it is carried to the wire mill.

Wire-Drawing.—Up to this point the product is known by the technical name of "rods," and it is only after it has been drawn down in the dies that it is known commercially as "wire." Wire-drawing has the advantage of permitting the production of a much smaller wire than could be produced under the rolls, while the very process of drawing down the wire greatly enhances its physical qualities, increasing the tensile strength to a truly remarkable degree. The wire-drawing machine consists of a stout bench, on which is mounted a strong cast-iron drum, on which the wire is wound as it is drawn through the plate. The draw-plates, or die-plates, as they are called, are stout blocks of cast steel which are perforated with conical holes, carefully gauged to the exact desired size of the wire. The holes have a slight taper, the wire, of course, entering at the larger end of the hole. The coil of wire is placed on a spool located on the floor of the shop near the bench, and the end of the wire having been swagged down is passed through the die-plate and attached to the drum, which then proceeds to wind up the wire until the whole coil has been drawn down. As the wire-drawing is done cold, it can be well understood that with several score of these machines running at the same time it requires very powerful motive power to drive the mill. An increasing quantity of wire is now drawn to special shapes other than round—some square, or flat, some of D-section, or with a groove, these being adapted to various mechanical uses. After it has been drawn down, it is necessary to remove the strains in the wire, and it is accordingly taken to the annealing room, where it is loaded into large annealing pots. After the pot is filled, it is carefully sealed with sand to exclude the air, and the wire is exposed to a steady heat for a period of from eight to nine hours. Of the total product, part is now ready for the open market without any further treatment, a small portion of it is sent to the galvanizing room to be galvanized and a large proportion of it goes to the nail mill to be made up into wire nails or barbed wire.

Nail Mill.—In the nail mill each separate machine is capable of turning out from 150 to 500 finished nails per minute. In front of each machine is a reel, upon which the coil of wire is placed. One end of the wire is led into the machine, and as the power is thrown on, one sees the wire disappear through a small hole in the massive vertical casting; while to the accompaniment of a rapid succession of blows, a stream of the finished wire nails begins to pour out of the side of the machine into small iron boxes placed to receive them. The wire first passes between two pairs of horizontal, grooved wheels, which are pressed firmly together to give the required tension to the wire as it is drawn into the machine after each finished nail has been formed and cut off. The nail is pointed by the action of a pair of pliers with V-shaped cutting edges and the head is formed up by the action of a very powerful cam-operated member, which strikes a hammer-like blow. As each nail is finished, the wire is gripped and enough of it drawn forward to form another nail. The 3-D fine nails are turned out at the rate of 500 per minute, and the large

60-D nails at the rate of 150 per minute. The boxes of finished nails are covered up and taken to big, revolving iron cylinders, known as rumblers, where they are rolled over and over, the nails being thrown against each other and against the sides of the cylinders and receiving that high polish which characterizes the finished product. The time during which they are treated in the rumblers varies according to the size and quality of the wire. A certain amount of sawdust is also used during this process in order to clean the nails thoroughly of grease and dirt. The nails are then loaded into 100-pound kegs, stenciled with the size and weight of the nails and the makers' name and taken to the warehouse.

Barbed Wire.—In a barbed wire shop coils of wire, carried on reels, are placed contiguous to the "barb" machines. The wire from two spools serves to form the strands, and the wire from the other two spools is used for the "barb." The two-strand wires, which are heavier than the others, are led between a pair of friction wheels, and drawn to proper tension. They are then met by the two other strands, which are led in transversely, one on either side. At stated intervals of a few inches, according to the spacing of the barbs, a pair of revolving fingers catch the two barb wires and give them a twist around one of the strand wires and at the conclusion of the twist two pairs of shears cut the ends of the barb diagonally, giving them the desired sharp points. The two wires next pass downwardly around an idler, and then horizontally into a combined winding and twisting frame. The frame itself revolves on a horizontal axis parallel with the machine, and serves by its revolution to twist the two strands. On a shaft arranged transversely within this frame is carried the barbed-wire spool, on which the finished product is wound ready for the market. When it is once started the operation is continuous and extremely rapid.

STEEL-WOOL, a material largely used as a substitute for sand paper or emery paper, for polishing metal or wood surfaces. It is simply a collection of very fine drawn steel wire waste or minute shavings made in turning steel, the result being a mass that looks and feels like wool, but on close examination what appear to be hairs are discovered to be very fine steel curlings.

STEEL-YARD. See **BALANCE**.

STEELE, Daniel, American Methodist Episcopal clergyman, and university president: b. Windham, N. Y., 5 Oct. 1824; d. 2 Sept. 1914. He was graduated at Wesleyan University in 1848 and held various pastorates until 1862. He was a professor at Genesee College, Lima, N. Y., in 1862-71, and in 1872, upon the organization of Syracuse University, he was elected its first president. He resigned later in that year, however, to resume work as a pastor at Boston. In 1884-93 he was professor at the Boston University School of Theology, after which he retired. He wrote 'A Commentary on Joshua' (1873); 'Milestone Papers' (1878); 'Commentary on Leviticus and Numbers' (1891); 'Jesus Exultant' (1899); 'Half Hours with Saint John's Epistles' (1901), etc.

STEELE, stēl, Flora Annie Webster, English novelist: b. Harrow, Middlesex, 2 April 1847. She lived in India until 1889, was provincial inspector of government and aided schools in Punjab, and for several years a member of the educational committee. She was married to a Bengal civilian in 1867. Her publications include 'Wide-a-Wake Stories' (1884); 'From the Five Rivers' (1893); 'Tales from the Punjab' (1894); 'On the Face of the Waters' (1895), a work of much power; 'The Host of the Lord' (1900); 'Voices in the Night' (1900), etc.

STEELE, Joel Dorman, American textbook author: b. Lima, N. Y., 14 May 1836; d. Elmira, N. Y., 25 May 1886. He was graduated at Genesee College in 1858, and was later engaged in teaching. He became a captain in the 81st New York Volunteers in the first year of the Civil War, saw service in the Peninsular Campaign and was severely wounded at Seven Pines. He was principal of the Newark, N. Y., High School in 1862-66; and of the Elmira Academy in 1866-72. He was thereafter engaged in preparing textbooks, in which occupation he was highly successful. He became a trustee of Syracuse University in 1872, and bequeathed \$50,000 to that institution to found a chair of theistic science. His textbooks were planned for periods of 14 weeks' study, and were widely used. He wrote 'Chemistry' (1867); 'Astronomy' (1868); 'Natural Philosophy' (1869); 'Geology' (1870); 'Human Physiology' (1873); 'Zoology' (1875); 'Barnes' Popular History of the United States' (1875). With his wife, Esther Baker Steele, he was author of a series of short histories: 'United States' (1872); 'France' (1874); 'Ancient Peoples' (1883); 'Medieval and Modern Peoples' (1883); 'General History' (1883); 'Greece' (1883); 'Rome' (1884).

STEELE, Sir John, Scottish sculptor: b. Aberdeen, 18 Sept. 1804; d. Edinburgh, 15 Sept. 1891. He received his art education in the Royal Academy, Edinburgh, and also in Rome. In the competition for a statue of Sir Walter Scott he was chosen to execute the seated figure for the Scott Monument in Edinburgh, and from the time of its unveiling (1846) his professional success was assured. Among his best known works, also in Edinburgh, are the statues of Wellington (1852), Professor Wilson, Allan Ramsay, Thomas Chalmers, Queen Victoria, and the Scottish memorial to the prince consort, on the completion of which (1876) the artist was knighted.

STEELE, Sir Richard, British author: b. Dublin, March 1672; d. Carmarthen, Wales, 1 Sept. 1729. He left Oxford without taking a degree, for some time rode as a private trooper in the dragoon guards, obtained an ensigncy in the foot guards, and wrote as his first comedy, the 'Funeral' or 'Grief à-la-mode,' which was acted in 1701, with considerable success. Through the recommendation of Addison, whom he had known at Charter-house, he was appointed, in the beginning of the reign of Anne, to the post of writer of the *London Gazette*. His comedy of the 'Tender Husband' (in which Addison had some hand) appeared in 1703, and his 'Lying Lover' in 1704. In 1709 he began the periodical paper so celebrated

under the title of the *Tatler* (q.v.). The majority of the papers in this periodical are by Steele, but a considerable number are wholly or partly by Addison, and one or two by other writers. Early in 1711 the *Tatler* was succeeded by the still more celebrated *Spectator* (q.v.). The *Spectator* terminating, Steele commenced, in March 1713, the *Guardian*, which was followed in October of the same year by a political periodical called the *Englishman*. By this time he had taken to active political life, having been returned to Parliament as member for Stockbridge in August 1713. In March 1714, he was expelled from the House for an alleged libel in the last number of the *Englishman*, and in another paper called the *Crisis*. On the accession of George I he received the appointments of surveyor of the royal stables, and governor of the king's comedians, and was knighted (1715). He again entered the House of Commons as member for Boroughbridge. Always engaged in some scheme or other, few or none of which succeeded, he wasted his regular income in the anticipation of a greater, until absolute distress was the consequence. In 1720 his patent as governor of the royal comedians was revoked. He appealed to the public, in a paper called the *Theatre*, which he had begun to publish at the beginning of 1720, a week or two before the event referred to. He was restored, the following year, to his authority over Drury Lane Theatre, and soon after wrote his comedy of the 'Conscious Lovers,' on a hint from Terence. This piece he dedicated to the king, who rewarded the author with £500. Consult the 'Life' by Aitken (1889) and by Dobson (1886), who also edited 'Selected Works' (1885).

STEELE, Sir Samuel Benfield, Canadian soldier: b. Purbrook, Ontario, 5 Jan. 1849. He was educated at the British American Commercial School and at the Royal Military School, Toronto. He served in the Fenian Raid in 1866; in the Red River Expedition in 1870; joined the Canadian Permanent Artillery in 1871, and the Royal North West Mounted Police in 1873, becoming its superintendent in 1885. He commanded a body of cavalry and scouts in the second Louis Riel Rebellion in 1885; and in 1898 he commanded the Royal North West Mounted Police during the Klondike gold rush. He served in Africa in the Boer War in 1899-1901, attaining rank as colonel; was administrator of the 10th and 13th military districts in Canada in 1907-10; and upon the outbreak of the European War in 1914 he engaged in organizing the troops of Manitoba. In December 1914 he was promoted brigadier-general with rank of major-general, and became inspector-general for western Canada. He organized, commanded and trained the Second Canadian Division in 1915; and in 1915-18 he commanded the Imperial and Canadian troops at Shorncliff. He was knighted in 1918. Author of 'Forty Years in Canada' (1915).

STEELHEAD, a fish. See SALMON.

STEELTON, Canada, town in Algoma District, province of Ontario, 10 miles northwest of Sault Sainte Marie, Mich., on the Algoma Central and Hudson Bay and the Canadian Pacific railways. There are manufacturing industries. Pop. 3,936.

STEELTON, stēl'ton, Pa., borough, Dauphin County, on the Susquehanna River, the Pennsylvania Canal, and on the Philadelphia and Reading and the Pennsylvania railroads, three miles east of Harrisburg. An electric line connects the borough with Harrisburg. In 1866 the place was laid out under the name of Baldwin; later it was called Steel-Works P. O., and in 1880 it was incorporated under its present name. The chief industrial establishments of the place are owned by the Pennsylvania Steel Company, which has bridge and construction works, several blast furnaces, and rail and blooming mills. Other manufactories are lumber mills, several flour mills, brick yards and machine shops. The public school was erected by the Steel Company. The national bank has a capital of \$75,000. Pop. 18,000.

STEEN, stān, Jan Havickz, Dutch painter: b. Leyden, 1626; d. 1679. He studied under Nicolas Knupfer, Van Ostade, and Van Goyen, and married the daughter of the latter. From the conflicting accounts of his career it appears that he was at one time a tavern-keeper, and the tradition is that he led a drunken and dissolute life; but in disproof of this his numerous paintings attest that he must have been a laborious and careful worker. He stands in the foremost rank among Dutch painters alike as regards execution, composition and color, and the action, gestures and expression of his figures, while his composition is always full of spirited suggestiveness and genial humor. In the British National Gallery he is represented by 'The Music Master,' but his chief paintings are to be seen in the galleries of The Hague and Amsterdam. Consult Van Westrhene, 'Jan Steen, Etude sur l'Art' (1856); Bode, W., 'Great Masters of Dutch and Flemish Painting' (New York 1909).

STEENSTRUP, stān'stroop, Johann Iapetus Smith, Norwegian zoologist and archaeologist: b. Vang, 8 March 1813; d. Copenhagen, 20 June 1897. From 1845 until his retirement from active duties in 1885 he was professor of zoology and director of the zoological museum at Copenhagen. He was a busy investigator and wrote treatises on a wide range of subjects, from parasitic crabs and the change in the position of the eyes in flounders, to peat-bogs and the prehistoric remains known as kitchen-middens. He wrote also 'Yak-Lungta Bracteaterne' (1892).

STEENWYCK, stān'vīk, Henrik van, Dutch painter: b. Steenwyck, 1550; d. Frankfurt-on-Main, 1603. He excelled in the execution of church interiors and was a master of both linear and aerial perspective. His son, Hendrik, called "the young Steenwyck," was born about 1589, and became the friend of Van Dyke, for whom he is said to have painted architectural backgrounds. He died in London, in what year is unknown, but it must have been subsequent to 1647.

STEEPLE, in architecture, any tower-like structure attached to a church, whether a tower proper or spire or a combination of tower and spire or tower and lantern. See SPIRE.

STEEPLE-BUSH. See HARDHACK.

STEEPLECHASING, horse racing over a rough course, so called from the fact that the riding involves steep hill climbing or that the riders had a distant church steeple as a goal

which they reached regardless of the country over which they might be obliged to travel. Steeplechase racing is most exciting, as the obstacles over which the horses are obliged to jump involves considerable danger. The Great National Steeplechase of Liverpool is a big English racing event. It was established in 1839. The Meadowbrook Club in the United States is the pioneer of steeplechasing.

STEERAGE, in passenger steamships, a section on or below the main deck that has common appointments and is assigned to the cheapest class of passengers. Since it is mainly occupied by immigrants and poor people, the term has acquired a literary sense equivalent to "common people." In a war-vessel the quarters of the junior officers, clerks, etc., fitted with lockers, mess tables, etc. The character of a vessel's response to her helm is also termed steerage. Steerage-way implies a sufficient degree of motion communicated to a ship for her to become susceptible of the effects of the helm in governing her course.

STEEVENS, stē'vĕnz, George, English Shakespearean critic: b. Poplar, London, 10 May 1736; d. Hampstead, 22 Jan. 1800. He was educated at Eton and King's College, Cambridge, but did not take a degree, and in 1766 published 'Twenty of the Plays of Shakespeare' in four volumes. After this he was associated with Dr. Johnson in an edition of Shakespeare published in 1773. He then prepared (1793) a corrected text, with notes of the dramatist's works, in 15 volumes, which long remained the standard edition. He made many enemies by his acrimonious and ill-natured attacks on contemporary editors and others, but his contribution to Shakespearean criticism has permanent value.

STEEVENS, George Warrington, English journalist: b. Seydenham, near London, 10 Dec. 1869; d. Ladysmith, South Africa, 15 Jan. 1900. He was graduated at both Oxford and London universities in 1892, and in 1893 he became a Fellow of Pembroke College, Oxford. In the summer of 1893, however, he abandoned his fellowship, and embarked upon a journalistic career in London. He had already contributed to the *National Observer* and other publications, and now joined the staff of the *Pall Mall Gazette*, also contributing to the *New Review* and to *Blackwood's Magazine*. Upon the establishment of the *Daily Mail* in 1895 he became a member of its staff, and it was as its correspondent on various missions in foreign countries that he established his reputation as a writer gifted with the power of vivid description and with a keen perception of salient points. He covered the McKinley-Bryan Presidential campaign in the United States in 1896; and his first experience as a war correspondent was with the Turkish army in the Græco-Turkish War in Thessaly in 1897. He was with Kitchener's army in Egypt in 1898, and wrote a brilliant account of the campaign. He was in India in the winter of 1898-99; and in 1899 reported the second trial of Captain Dreyfus at Rennes. In September 1899 he went to South Africa as the *Daily Mail's* correspondent. He was with Sir George White at the defense of Natal, and at the siege of Ladysmith, where he died of enteric

fever. He wrote 'The Land of the Dollar' (1897); 'With the Conquering Turk' (1899); 'Egypt in 1898' (1899); 'With Kitchener at Khartoum' (1899); 'From Capetown to Ladysmith' (1900).

STEFÁNSSON, stā'fān-sōn, Vilhjálmur, Arctic explorer: b. Arnes, Manitoba, Canada, 3 Nov. 1879. He received his education at the State University of North Dakota and the State University of Iowa. In 1903-04 he studied at the Harvard Divinity School, and in 1904-06 at the Harvard Graduate School. His early years were spent on a farm; in 1893-96 he was a cow-boy; at different times he was employed as school teacher, life insurance agent, organizer of secret society lodges, public lecturer, reporter on the Boston *Evening Transcript*, city editor of the *Plainedealer*, Grand Forks, N. D., and assistant instructor in anthropology at Harvard University. In 1904 he undertook a private expedition to Iceland and in 1905 undertook an archaeological expedition to Iceland for Harvard University. In 1906-07 he made an ethnological expedition to the Eskimo of the mouth of the Mackenzie River and northern Alaska for the universities of Harvard and Toronto. He undertook a second Arctic expedition under the auspices of the American Museum of Natural History and the Geological Survey of Canada, accompanied by Dr. Rudolph M. Anderson, zoologist, in 1908-12; made investigations and collections in geography, geology, ethnology, archaeology, zoology, botany, etc., reported so-called blond Eskimo found on both sides of Dolphin and Union straits and Coronation Gulf and visited several tribes whose ancestors had never and who themselves had never seen a white man. Stefánsson was commander of the Canadian Arctic expedition which sailed from Victoria, British Columbia, in June 1913, for four years of exploration north of Canada and Alaska. With two companions he crossed Beaufort Sea on moving ice from Martin Point, Alaska, to the northwest corner of Banks Island. With three companions he explored the sea west of Prince Patrick Island to the north of which he discovered a new land in 1915. In September 1915 he left Cape Bathurst with the schooner *Polar Bear*, outfitted for two years' further exploration of land already discovered, and seas to the west and north. He returned in 1918, and in the same year was awarded the Charles P. Daly medal of the American Geographical Society. V. Stefánsson has published 'Arctic Search' (1913); 'My Life with the Eskimo' (1914); and many scientific articles in journals of anthropology, folklore, philology, geography; also popular articles on literature of Iceland in *Poet-Lore* and on the Eskimo and Arctic travel, chiefly in *Harper's Magazine* after 1906.

STEFFANI, stā-fā-nē, Agostino, Abbate, Italian composer: b. Castlefranco, Venice, 1655; d. Frankfort-on-Main, 1730. He received his musical training in Venice and Munich, in which latter city he was appointed director of the Grand-ducal Concerts (1681), and, after the production of his opera 'Servio Tullio' in 1688, chapel master to the court of Hanover. In that capacity he did much to improve the religious music of his day. His Italian operas, which were produced with brilliant stage setting at Herrenhausen Castle, were also translated

into German and performed at Hamburg (1690). Fine as are his operas, his chamber music, much of it set to Italian words, is even richer in melody and tonal expression. Later in life he became more and more engrossed in his diplomatic duties, resigned to Handel his office of chapel master (1710), and was appointed councillor by the Grand-duke Palatine, and, by the Pope, prothonotary and bishop of Spizza (*in partibus*). He applied himself henceforth to his civil and religious functions, in pursuance of which he made his last visit to Italy in 1729. His works include 'Psalmody Vespertina, for Eight Voices' (1674); 'Sonate da Camera a due violine, alto e continuo' (1679); 'Duetti da Camera a soprano e contralto' (1683), etc.

STEFFENS, Joseph Lincoln, American author: b. San Francisco, Cal., 6 April 1866. He was graduated at the University of California in 1889 and later studied at the universities of Berlin, Heidelberg, Leipzig and Paris. He was connected with the New York *Evening Post* in 1892-98; was city editor of the New York *Commercial Advertiser* in 1898-1902; managing editor of *McClure's Magazine* in 1902-06; and editor of the *American Magazine* and of *Everybody's Magazine* in 1906-11. He is well known as a contributor of short fiction and special articles to magazines. Author of 'The Shame of the Cities' (1904); 'The Struggle for Self-Government' (1906); 'The Uplifters' (1909); 'The Least of These' (1910).

STEGOCEPHALIA, one of the primary divisions of the amphibia, sometimes considered as a sub-class, sometimes as an order, especially characterized by the great development of dermal or superficial bones on the dorsal surface of the head. Being totally extinct and consequently known only from their skeletal remains many questions concerning their relationships continue open. Many of the stegocéphali were of salamander-like form, with broad, flattened head, simple, weak paired limbs of the typical pentadactyl type and a more or less elongated tail. Some were lizard-like with stronger limbs. Some, like *Ophiderpeton*, lacked limbs and were serpentine in form. Many are known to have passed through branchiate larval stages and some, like the *Branchiosauridae*, retained the gills throughout life. Many of the large labyrinthodonts had rudimentary tails and must have been somewhat frog-like in aspect. One remarkable form, the *Dissorophus multicinctus* from the Permian formation of Texas, is described by Professor Cope as having borne an armadillo-like carapace on the back. The roofing bones of the head were numerous and covered the temporal fossa as well as the cranium. In some of the larger forms they were much sculptured and excavated for the accommodation of mucous canals. The large eyes were supported by a ring of sclerotic bones, found well developed at the present day only in the eyes of some birds. In the middle of the cranial roof between the two parietal bones was the conspicuous pineal foramen supposed to have lodged a functional median eye. The nostrils were situated near the tip of the snout and the internal nares in the anterior part of the palate. The base of the skull was imperfectly ossified, but there was a well-developed basi-occipital bone with usually two occipital condyles. This

deficiency of bone was supplied by the large superficial parasphenoid. The lower jaw was complex and the occurrence of an infradentary bone is especially noteworthy. Teeth of a simple, conical, partly hollow form, or with the walls fluted or, as in the labyrinthodonta (q.v.), complexly folded, existed on the jaws and palate. The notochord generally persisted and the vertebræ consisted of mere bony shells or were better ossified and formed of alternating intercentra and pleurocentra supporting the hæmal and neural arches or were otherwise segmented. There was never more than a single sacral vertebra. Scapula, coracoid, clavicle and interclavicle were always present in the shoulder girdle and traces of a sternum sometimes appear. Likewise an ischium, ilium and occasionally a pubis have been found on each side of the pelvis. Both fore and hind limbs were simple and salamander-like, the carpus and tarsus unossified in the smaller species and presenting all of the primitive elements with two or three centralia in *Archegosaurus* and other larger forms. Ribs were simple and never joined the sternum. Some forms like *Branchiosaurus* were covered with an armor of scales.

The stegocephali were the first vertebrates to leave the water and assume more or less completely terrestrial habits; they were the first whose limbs departed from the fin type and became pentadactyl; their nasal passages show that they breathed air and they probably had lungs; their teeth indicate a flesh diet, probably consisting chiefly of fish. Footprints of stegocephali are found in abundance in rocks representing the muddy shores of the Carboniferous Period and remains of these creatures are found from the Lower Carboniferous through the Permian and in the Triassic in Europe and America. They are especially abundant in the Permian of Texas from which many interesting forms have been taken. Palæontologists differ on the question of their origin, some considering them descendants of the crossopterygians, others of the Dipnoans. Whatever their origin the stegocephali formed the starting point for all terrestrial and air-breathing vertebrates, probably first giving rise to primitive reptiles like the cotylosauria, becoming themselves extinct. Consult Credner, 'Die Urvierfüssler'; 'Naturw. Wochenschrift' (Berlin 1891); Cope, 'American Naturalist' (1884); Woodward, 'Vertebrate Palæontology' (Cambridge 1898); Knipe, H. R., 'Evolution in the Past' (London 1912).

STEGOSAURIA, a group of dinosaurs (q.v.).

STEIN, stĭn, **Charlotte von**, German writer, friend of Goethe (q.v.): b. Weimar, 25 Dec. 1742; d. there, 6 Jan. 1827. She was married in 1764 to the duke's master of the horse. Her friendship with Goethe was broken suddenly after his return from Italy (1788). Goethe's 'Letters' to her were first published in 1848-51, edited by Schott. Their almost perfect friendship for 10 years is believed to have profoundly assisted Goethe in his work. A final collection was printed by the Goethe Society in 1886. She wrote a tragedy 'Dido' (1867; ed. by Duntzer). Consult the 'Life' by Duntzer (1874).

STEIN, Heinrich Friedrich Karl, German statesman: b. Nassau, 26 Oct. 1757; d. Kappenberg, Westphalia, 29 June 1831. He studied at Göttingen, entered the mining department of the Prussian government, became head of the mines and manufactures (1784) department in Westphalia, visited the mining districts of England in 1786, became president of the provincial chambers of Westphalia in 1796, and a minister of state in 1804. For the severity of his criticisms on the administration he was dismissed (1807), but in a few months he was recalled, with power to introduce his reforms. Accordingly he abolished serfage by edict, made military service obligatory on all classes, and rearranged the financial and administrative affairs. By means of these reforms he laid the basis of Prussia's future greatness, but in less than a year he was proscribed by Napoleon and dismissed from office. He afterward visited Saint Petersburg, and was instrumental in bringing about the coalition which crushed Napoleon. When the military struggle was over he spent his life in retirement. Consult Pertz, 'Das Leben des Ministers Freiherrn von Stein' (1849); Stern, 'Stein und sein Zeitalter' (1855); Seeley, 'Life and Times of Stein' (1878); Meier, 'Die Reform der Verwaltungsorganisation unter Stein und Hardenberg' (1881); and the popular biographies by Neubauer (1894) and Bauer (1895).

STEIN, Sir Mark Aurel, British Orientalist and archæologist: b. Budapest, Hungary, 26 Nov. 1862. He was educated at the universities of Vienna, Tübingen, Oxford and London. He was registrar of the Punjab University and principal of the Oriental College, Lahore, India, in 1888-99, and in 1899 he became principal of the Calcutta Madrasah. The Indian government sent him to conduct archæological investigations in Chinese Turkestan in 1900-01, and he was afterward appointed inspector of education in the Punjab. He was engaged in archæological investigations in central Asia and western China in 1906-08, and in 1909 he became connected with the archæological department of India. He received the gold medal of the Royal Geographical Society in 1909. He published a critical edition, with an English translation, of Kalhana's 'Rājatarangini, or Sanskrit Chronicle of the Kings of Kashmir' (2 vols., 1900); and is author of 'The Sand-Buried Cities of Khotan' (1903); 'Ancient Khotan' (2 vols., 1907); 'Ruins of Desert Cathay' (2 vols., 1912), etc.

STEINER, stī'nēr, Bernard Christian, American educator: b. Guilford, Conn., 13 Aug. 1867; prepared for college at the Frederick (Md.) Academy; was graduated at Yale A.B. 1888, A.M. 1890; was a Fellow in history at Johns Hopkins, 1890-91 and Ph.D. 1891; instructor in history at Williams College, 1891-92; instructor of history at Johns Hopkins, 1893, and associate there from 1894 to 1911. He was graduated at University of Maryland with degree of LL.B. in 1894; was dean and professor of constitutional law, Baltimore University, 1897-1900, and was dean and professor of public law in the Baltimore Law School from 1900 to 1904. Since 1892 he has been librarian of the Enoch Pratt Free Library of Baltimore City. His publications include 'Education in Connecticut' (1893); 'Education in Maryland'

(1894); 'Citizenship and Suffrage in Maryland' (1895); 'Institutions and Civil Government of Maryland' (1899); 'Life of James McHenry' (1907); 'Life of Reverdy Johnson' (1914), etc.

STEINHAUER, Henry Bird, Canadian Chippewa Indian clergyman and missionary: b. Ramak Indian Settlement, Lake Simcoe, Ontario, 1804; d. Whitefish Lake, Ontario, 29 Dec. 1885. He was adopted and educated by a German family, and about 1840 he accompanied a Methodist missionary, Rev. James Evans, to the Canadian Northwest. He was at Norway House with Evans for about 15 years, acting as Cree interpreter and assisting the missionary in his task of forming symbolic characters for the Cree language. He was afterward ordained in the Methodist Church and established a mission at Whitefish Lake, where he labored until his death. He translated nearly all of the Bible into the Cree language.

STEINHEIL, stīn'hil, Karl August, German physicist and astronomer: b. Rappoltsweiler, Alsace, 12 Oct. 1801; d. Munich, 12 Sept. 1870. After completing a course in law at the University of Erlangen, and courses in astronomy at Göttingen and Königsberg, he was appointed to the chair of physics and mathematics in the University of Munich. He later entered the service of the Austrian government, becoming especially noted for his development and perfection of the telegraph system, a service which he also rendered to the Swiss government a few years later. In 1836 he built the first printing telegraph, invented an electromagnetic telegraph, the electrical clock, a special pyroscope, and brought out the first daguerreotype picture in Germany. He also invented several optical instruments, and in 1854 began the manufacture of optical, astronomical and photographic materials, and it was in his factory that the telescopes for the observatories of Upsala, Mannheim, Leipzig, etc., were made. Steinheilite or iolite, a transparent mineral, was named after him.

STEINHEIL, Louis Charles Auguste, Alsatian painter: b. Strassburg, 26 June 1814; d. Paris, 17 May 1885. He studied with Decaisne and painted in nearly every medium, but gave especial attention to glass painting and church decoration. In 1876 he was commissioned to execute frescoes in the cathedral of Strassburg. Among his works are 'Saint Philomela' (1841); 'Mother' (1847), Nantes Museum.

STEINHEIL, Marguerite, French woman, central figure in a mysterious *cause célèbre*: b. Beaucourt, 16 April 1869. She came of a wealthy family named Japy and was married to Adolphe Steinheil, an artist. They lived in Paris, where Mme. Steinheil became prominent in a distinguished circle, including many of the most famous Parisian lights in politics, art and literature. She was on terms of intimacy with President Faure, and gossip connected her with his sudden death, but no proof was ever produced. On the night of 30-31 May 1908 Mme. Steinheil's husband and her mother, Mme. Japy, were murdered and robbed and Mme. Steinheil herself was found bound and gagged upon a bed. She was later accused of committing the crime, but was acquitted after a sensational

trial. There were rumors of political complications, enhanced by a mysterious pearl necklace supposed to have been given her by President Faure. How much or little of truth was in the rumors and accusations rife at the time of the trial has never become known, and no light has ever been thrown upon the crime of which she was accused. After her acquittal she lived in England in retirement. Author of 'My Memoirs' (New York 1912).

STEINITZ, William, German-American chess player: b. Prague, Bohemia, 14 May 1836; d. New York, 12 Aug. 1900. He was educated at Prague and Vienna and early became famous as a chess player, taking prizes at Vienna in 1859, 1860 and 1861. In 1862 he won sixth prize in an international match at London and in 1866 took the first prize in the tournament of the British Chess Association. In the same year he defeated Anderssen in a set match for the world's championship, which he held for 28 years. He later won championship matches from Zukertort, Tchigorin and others. At the Vienna international tournament of 1873 he beat the world's record by winning 16 straight games. That year he settled in London, but in 1882 removed to the United States. During 1885-91 he edited the *International Chess Magazine*. In 1894 he lost his first great match and the championship to Emmanuel Lasker (q.v.). A return match in 1897 was also lost, after which date he ceased playing serious chess. He more than any other player originated the modern school of winning by accumulating minute advantages instead of by grand strategy and combination. He published 'The Modern Chess Instructor' (1889).

STEINMETZ, stin'mets, Charles Proteus, American electrician: b. Breslau, Germany, 9 April 1865. He was educated at Breslau, Zürich and Berlin, specializing in mathematics, electrical engineering and chemistry. In 1902 Mr. Steinmetz received the degree of A.M. from Harvard University and in 1903 the degree of Ph.D. from Union University. Since 1893 he has served as consulting engineer of the General Electric Company and since 1902 has in addition held the chair of electrophysics at Union University. Mr. Steinmetz is also Socialist president of the City Council and president of the Board of Education of Schenectady. He is one of the greatest scholars and scientists in the electrical field to-day and his researches have done much to further the progress of applied industrial chemistry. His works include 'Theory and Calculation of Alternating-Current Phenomena' (1897; 5th ed., 1916); 'Theoretical Elements of Electrical Engineering' (4th ed., 1915); 'Theory and Calculation of Transient Electric Phenomena and Oscillations' (1909; 2d ed., 1911); 'General Lectures on Electrical Engineering' (5th ed., 1917); 'Radiation, Light and Illumination' (1909; 2d ed., 1911); 'Engineering Mathematics' (1910; 3d ed., 1917); 'Electric Discharges, Waves and Impulses' (1911); 'America and the New Epoch' (1916); 'Theory and Calculation of Electric Circuits' (1917); 'Theory and Calculation of Electrical Apparatus' (1917), also sundry mathematical papers on theoretical, experimental investigations in electric engineering.

STEINMETZ, Karl Friedrich, Prussian military officer: b. Eisenach, 27 Dec. 1796; d. Landeck, 4 Aug. 1877. He entered the army in 1812 and fought during the Napoleonic campaigns of 1813-15. In 1848 he commanded a regiment of the Royal Guards at Berlin and gained distinction in his encounters with the populace. The same year he fought in the Danish campaigns. In the Austrian War of 1866 he commanded the fifth army corps and defeated the Austrians in three successive engagements at Nachod, Skalitz and Schweinschäld, 27-29 June. At the outbreak of the Franco-Prussian War he was appointed, in July 1870, to command of the right wing operating in the neighborhood of Metz against Bazaine, and fought at Spichern, Colombey-Nouilly and Gravelotte. At this time friction arose with other officers and he asked to be relieved of his command, which was granted in September 1870, and he was appointed governor-general of Posen and Silesia. The following year he was made field-marshal.

STEINTHAL, stin'täl, Heymann, German philosopher and philologist: b. Gröbzig, Anhalt, 16 May 1825; d. 1899. He was distinguished as a follower of the Herbartian ethical school, maintaining that the psychology of society combined with comparative philology yielded the best results toward the solution of human problems. His philosophy was allied with that of Moritz Lazarus who was co-editor with him of *Zeitschrift für Völkerpsychologie und Sprachwissenschaft* from 1859 to 1890. In philology he followed the methods of Wilhelm von Humboldt whose work he elucidated in several books in 1848, 1864, 1867 and an edition in 1884. He studied and was graduated at the University of Berlin in 1850; from 1852-55 studied Chinese language and literature in Paris; in 1863 became extraordinary professor of philology in Berlin; and after 1872 lecturer at the school of Judaism there on the history and philosophy of religion. His chief works are 'Der Ursprung der Sprache im Zusammenhang mit den letzten Fragen alles Wissens' (1851; 4th ed. 1888); 'Klassifikation der Sprachen' (1850); 'Charakteristik der hauptsächlichsten Typen des Sprachbaues' (1860); 'Die Entwicklung der Schrift' (1852); 'Grammatik, Logik, Psychologie, ihre Prinzipien, etc.' (1885); 'Geschichte der Sprachwissenschaft bei den Griechen und Römern' (1863; 2d ed., 1889-91); 'Die Mande-Negersprachen, psychologisch und phonetisch betrachtet' (1867); 'Abriss der Sprachwissenschaft' (2d ed., 1881); 'Allgemeine Ethik' (1880); 'Zu Bibel und Religion-philosophie' (1890-95); 'Ueber Juden und Judentum,' ed. by Karpeles, posthumous essays, appeared (1906). Consult Achelis, 'Heymann Steintal' (Hamburg 1898); and 'Wie Steintal und Lazarus Brüder werden' a memorial essay by his widow in 'Jahrbuch für jüdische Geschichte und Literatur' (1900).

STEINWAY, stin'wā (originally **STEINWEG**), **Henry Engelhard**, American piano manufacturer: b. Wolfshagen, Germany, 15 Feb. 1797; d. New York, 1871. He learned organ-building and piano-making and established a business at Seesen, near the Harz Mountains, but emigrated to the United States in 1849, and with his three sons was employed

in various piano factories in New York. In 1853 he founded the firm of Steinway & Sons, and in 1855 exhibited a square piano in which the American iron frame was combined with an overstrung scale, the first example of the Steinway system. About 1866 the Steinways began to make upright pianos; their instruments exhibited at the Universal Exhibition of 1867 became models for Continental manufacturers, while later improvements have enabled the firm to take rank with the famous older makers of Europe.

STEJNEGER, Leonhard, American naturalist: b. Bergen, Norway, 30 Oct. 1851. He was graduated at Frederick's University, Christiania, in 1875, and came to the United States in 1881. He went on a natural history expedition to Bering Island and Kamchatka for the United States National Museum in 1882-83, and was appointed assistant curator of that institution at Washington in 1884; he became curator of reptiles there in 1889 and head curator of biology in 1911. Author of 'Poisonous Snakes of North America' (1893); 'Report of the Rookeries of the Commander Islands' (1897); 'The Asiatic Fur Seal Islands and the Fur Seal Industry' (1898); 'The Herpetology of Porto Rico' (1904); 'The Herpetology of Japan' (1907); 'The Origin of the So-Called Atlantic Animals and Plants of Western Norway' (1907), etc.

STELLA MIRA. See MIRA.

STELLARTON, Canada, town in Pictou County, Nova Scotia, on the East River, 75 miles northwest of Halifax, on the Intercolonial Railway. It is situated in a coal-mining region and has manufacturing interests. Pop. 3,910.

STELLHORN, Frederick William, American Lutheran theologian: b. Hanover, Germany, 2 Oct. 1841. He was graduated at Concordia College, Fort Wayne, Ind., in 1862, was ordained to the Lutheran ministry in 1865 and held two pastorates, 1865-69. He was a professor at Northwestern University, Watertown, Wis., 1869-74, at Concordia College, 1874-81, and has been professor of theology at Capital University, Columbus, O., since 1881, and dean of the theological seminary of the same institution since 1903. He has published 'Kurzgefasstes Wörterbuch zum Griechischen Neuen Testament' (2d ed., 1905); 'A Brief Commentary on the Four Gospels' (1891); 'Annotations to the Acts of the Apostles' (1896); 'The Error of Modern Missouri' (1897); 'Die Pastoralbriefe Pauli übersetzt und erklärt' (2 vols., 1899); 'Paul's Epistle to the Romans Briefly Explained' (1899); 'Schriftbeweis des Lutherischen Katechismus' (1912). With a brief intermission he was editor of *Lutherische Kirchenzeitung* 1881-98, and has been editor of *Theologische Zeitblätter* since 1882.

STELLITE, name applied to a series of alloys consisting essentially of cobalt and chromium. The alloy consisting of cobalt and chromium only is made by melting the two metals together and casting the resulting mixture into bars. If the chromium does not exceed 25 or 30 per cent, these bars may be forged into rods or rolled into sheets. During the cast-

ing and rolling process the alloy becomes covered with a thin film of oxide of a dark blue-black color. When this is ground off, however, and the rod or plate is polished, it shows a beautiful lustre which is not dimmed by exposure to any kind of metal conditions. It remains perfectly bright in moist air, and even in the atmosphere of a chemical laboratory. In fact it retains its lustre under all circumstances and is only equaled in this respect by gold and the metals of the platinum group. It may be readily forged into spoons, knives, forks, etc., and these articles are so hard that they can scarcely be scratched by the file. The alloy is stiffer than steel. In fact it is the most rigid alloy in use and, while its elastic limit is not very high, it is sufficient for practical purposes in almost any form into which it may be made. When a certain amount of tungsten or molybdenum is added to the alloy, the hardness is greatly increased, and some of the alloys thus formed are harder than any steel ever produced. These latter are termed tool metal alloys, and when cast into bars need only to be ground to a cutting edge and placed in the tool holder of the lathe to render them immediately available. Results obtained with these tools in the machine-shop are very remarkable. Red hot shavings may be cut from steel bars without injury to the edge of the tool, and on certain kinds of work a machinist is able to turn out from 25 to 100 per cent more work in a day than with the best high-speed steel tools. The name stellite is derived from the Latin word *Stella*, meaning a star, because when once polished it always retains its lustre or brightness. Stellite alloys have been manufactured into pocket and table cutlery, spoons, forks, mirrors, razors, knife edges for balances, surgical tools, dental instruments and machine tools. Pocket knife blades made of this metal retain their lustre under all circumstances, and may be used for cutting apples, oranges, lemons and various other fruits without marring their lustre in the slightest degree.

STELVIO, stě'vê-ô, Austria, a lofty Alpine pass (9,055 feet), between the Tyrol and Lombardy, forming part of the great military road from Milan to Innsbruck, completed by the Austrian government in 1824, at a cost of \$1,500,000. It is 33 miles long, and its bridges and causeways, and terraces cut in the rock are especially noteworthy. The pass is remarkable for its views and the grandeur of its scenery. It can only be utilized in the summer season.

STELZLE, Charles, American Presbyterian clergyman and sociologist: b. New York, 4 June 1869. He was for some years a machinist, studied at the Moody Bible Institute in 1894-95, and in 1895 became pastor of Hope Chapel, Minneapolis, Minn. He was ordained in 1900, and held various pastorates until 1903, when he became superintendent of the Presbyterian Department of Church and Labor, a division of the Home Mission Board. He was organizer and in 1910-12 was director of the Labor Temple in New York; is director of the department of Christian sociology in the Bible Teachers' Training School, New York; investigated the economic aspect of the liquor problem in the United States and Europe in 1914-15; and with a staff of investigators made

social surveys of 200 American cities. Author of 'The Workingman and Social Problems' (1903); 'Messages to Workingmen' (1906); 'Principles of Successful Church Advertising' (1909); 'The Church and Labor' (1910); 'The Call of the New Day to the Old Church' (1915); 'Why Prohibition' (1918), etc.

STEM, the main axis of a plant. Stems usually bear foliar organs, such as leaves, but in the carrion-flower (*Stapelia*) and in some other plants no leaves are produced; and in cacti the leaves are rarely observed because they are early deciduous. Though there are stem-like organs among the algae and fungi (*Thallophytes*) and liverworts and mosses (*Bryophytes*), true stems are found only among the club-mosses, horse-tails and ferns (*Pteridophytes*) and the flowering plants (*Spermatophytes*). In the last-named group the stems are produced by the development of the embryonic plumule, and reach their maximum size in the California redwood which becomes more than 350 feet tall and may exceed 20 feet in diameter.

Stems are very diverse in general habit; they may be erect and unbranched as in most palms; erect and branched as in pine and many other trees; scrambling as in blackberries and raspberries; twining as in morning-glory and hop; climbing as in grape and Boston ivy; creeping as in dewberry and periwinkle; and with many modifications of these general types. They are also definable according to duration as annual and perennial; and according to structure as herbaceous and woody. These are also modified in nature.

Botanists favor a classification which deals with the character of foliar organs borne, thus: (1) leaf-bearing stems, generally most evident since they bear leaves, and consequently aerial and frequently branched; (2) flower-bearing stems; and (3) scale-bearing stems, which bear rather small, more or less leaf-like but not green organs, and may be situated above or below the surface of the soil. The last group runs into many modifications, such as rhizomes, tubers and bulbs below ground, and the buds of trees and shrubs above ground. They are also grouped according to their anatomical structure, as described later.

The functions of stems are usually to lift the leaves and flowers off the ground and expose them to light and air, or to act as storage-organs in which reserve food is placed until needed. While the epidermis remains green, aerial stems can, and do, perform the functions of leaves in assimilating food, a very important office in such plants as cacti. In function the stems may be sharply contrasted with roots or descending axes; but none of these are constant, there being exceptions. Thus, most stems have chlorophyll (q.v.) which is almost never present in roots, except a few aerial ones; stems usually bear leaves, roots do not; the stem-tip is almost invariably a naked growing point, a root-tip is generally protected by a root-cap; stem-branches are superficial outgrowths (exogenous buds), root-branches develop endogenously from an internal layer; and usually stems and roots take opposite directions with respect to gravitation. In describing aerial stems the positions of leaves (nodes) are distinguished from parts which are leafless (internodes); the

buds which appear in the axils of the leaves (axillary) from those which are terminal (apical) or which appear arbitrarily (adventitious), etc. The method of branching is also important in classification, as lateral, false dichotomous, dichotomous, etc.

The internal structure of a stem may be understood by examining twigs of a dicotyledonous tree such as oak. The bark peels off and leaves a white woody cylinder. At the place where bark and wood separate is a more or less mucilaginous layer of cells (cambium) which are readily ruptured. This layer is responsible for growth in girth, since its cells are actively dividing during the growing season, forming bark layers externally and wood layers internally. It is also from this layer that the healing of wounds in the stem is conducted. The formation of the "callus" in cuttings and the union of grafts is also a function of this layer; hence its importance from the forester's and horticulturist's standpoint. When a ring of bark, which is usually found in three layers (outer, middle and inner), is removed, but the wood is uninjured, the leaves will not wither; hence the conclusion that the water ascends through the wood. If the ring be through the young wood the leaves will wither; hence the deduction that the ascent of water is through the young wood. This conclusion is corroborated by the fact that trees will flourish after the heart-wood has decayed. The descent of food to the roots and to other places where it is needed for growth or for storage is through the layers just outside the cambium (the inner bark). By means of the microscope and thin sections of stems a great variety of structures are revealed. Commencing with the growing-point there is found an external epidermis and an almost homogeneous internal structure of "fundamental tissue." This latter becomes more and more differentiated in parts more remote from the tip. Firm strands (fibro-vascular bundles) are usually first observed arranged radially in dicotyledonous plants. They consist of an internal woody part (xylem) and an external bast part (phloem) and between each pair a persistent layer of cambium. Each bundle terminates in a leaf above, becomes connected with others lower down and terminates below in the little rootlets. In the internal structure of the stems of dicotyledonous trees they constitute the wood. Between them are plate-like structures extending, in cross section, like the spokes of a wheel from various points at, near or remote from the centre to or toward the circumference. The fundamental tissue continues undifferentiated in the cambium, slightly modified in the pith, if there be any pith, and in the medullary rays. In monosotyledonous plants the fibro-vascular bundles are scattered in the fundamental tissue, pursue a curved course (inward and outward) and are collateral. The cambium being consumed at an early period of growth accounts for the usually uniform or very slightly tapering stems of plants belonging to this group — bamboos, grasses, etc. — and also for the non-separation of the bark from the generally thin layer of wood which surrounds a mass of pith or a hollow space. The development of growth in these plants is not marked by annual rings as in the dicotyledons.

From an economic standpoint, stems are of wide importance. Various underground stems are used for food, for example, potato, sweet potato, Jerusalem artichoke, onion, asparagus, kohlrabi, etc. Others are used as condiments such as ginger, licorice, cinnamon, sassafras, etc. Many furnish valuable fibres such as hemp, flax, jute, ramie, etc. Others are employed in tanning, as the barks of oak, chestnut and hemlock. The pith of many, such as sago, are used for food. The juices of others furnish rubber, palm wine, pulque, arrack and various oils. But the most important commercial uses made of stems are probably as timber and lumber, for which the dicotyledonous trees are most widely employed, as will be sufficiently clear from the above discussion. Consult any treatise on botany, as Lang's English edition of 'A Text-book of Botany,' by Strasburger and others (New York 1903).

STENCILING, a mode of decorating or marking with paint or ink, in which the design is formed through the spaces of a pattern. The design or pattern is cut out in a sheet of paste-board or a thin plate of metal called a stencil, which is applied to whatever is to be marked. The paint or other coloring matter is then laid freely over the stencil by means of a brush, and after the stencil is removed the design remains marked out on those parts of the surface which the coloring matter has reached through the spaces left in the stencil.

STENCILS. A stencil is a thin metal plate or a fibrous or waxed sheet of paper bearing wording or a design formed by cutting through the plate or the chemical coating or waxed surface of a paper sheet, or by embossing the wording upon a thin metal plate. The stencil is used to reproduce quickly characters, designs or wording by rubbing or pressing through the cut portions specially prepared stencil ink or stencil paste, or, in the case of embossed stencils, striking the paper against an inked ribbon covering the raised letters.

Stencils have been in use for several centuries as a means of marking characters upon certain objects. Formerly they were extensively used in making ornamental designs for stamping wood, cloth and paper material or imitating natural pictorial work upon friezes, panels and pottery. The Japanese for hundreds of years have practised the art of stencil making, while the Egyptians and Romans were well versed in it also. It is claimed that the Japanese learned the craft from the Chinese, who, perhaps, can be credited as being one of the first originators. These early stencils were probably not made of metal but of some tough fabric, paper or wood. The metal stencils used so extensively to-day in commercial trades have been developed from the pictorial stencils only within the past 50 years or so. We have definite knowledge that during our Civil War stencil-cutting was practised in America, the stencils being used for marking packing boxes and other shipments, and were cut in metal in about the same manner as stencil cutters cut them now. From that time there has been a huge demand for commercial stencils, as they can be made quickly, economically, and pleasing to the eye. They can be made very small or extremely large, their size being governed only by the dimensions of the metal sheet or the object upon

which they are to be imprinted. Any lettering, brand, trademark or other design can be made into stencil form and as such can be reproduced upon any suitable object by placing it against this object and brushing in the letters or design with stencil paste. Being cut from sheet metal, stencils naturally are durable and conveniently handled. The most artistic stencils are those that are laid out by an experienced stencil cutter who is talented in making good designs. This man will sketch out his lettering or design on a piece of sheet brass, copper or zinc, with a pencil, and then cut out the perfected design with special stencil chisels. Thirty or 40 chisels of various curves and sizes and straight chisels from one-thirty-second to one and one-quarter inch wide are used for this purpose, the cutter placing the sheet metal upon a block of lignum vitæ and chipping out the metal in the design, leaving occasional strips of metal, known as ties or stays, so that the design or letters will hold together. Ordinarily, lettering from one-quarter inch to one and one-half inches is usually cut with stencil dies. These stencil dies are steel punches, each bearing a letter of the alphabet or one of the numerals, and, when driven into the sheet metal with a blow of a hammer, will cut out the selected letter or figure. By using a series of these stencil dies, words can be quickly cut into the metal in letters of various heights if desired. The stencil can then be flattened by burnishing it or going over it with a special instrument called a "slapper" and then smoothing it with the mallet on the stencil block. Stencils for commercial use are frequently made by a special type of machine which cuts letters out of oil board or paste board. Such stencils are less durable than metal and necessarily bear only the one style of lettering. Stencils for transferring patterns, as in embroidery, are usually made upon heavy paper, the lines of the design being indicated by small holes pierced through the paper. For wall decorations, either the cut or the perforated stencils are used, the design being cut by hand with sharp knives of various shapes in thin metal, lead foil, tin foil, or prepared paper held against a piece of plate glass.

Another kind of stencil is the waxed paper which is used in mimeograph work and the dermatype stencil, a chemically coated fibrous sheet of great toughness which is converted into a stencil by the impression of type or stylus. With this form of stencil, the fibrous sheet is prepared ready for use of a size about the dimensions of the typewriter paper. It is inserted in the typewriter and a liquid is applied to it with a brush, when it is ready for the type matter. With the ribbon of the typewriter removed or held away from contact with the keys by an attachment usually fitted to typewriters, the pressure of the keys separates the chemical coating on the fibrous sheet. After all the wording required is typed on the sheet, the latter is removed and spread over an inked cylinder of a hand or motor-driven press. Paper of about the usual typewriter size is run between this cylinder and a platen roller, in which operation a small amount of ink is squeezed through all of the places in the fibrous sheet where the typewriter keys have made an impression, which brings out all the letters on the sheet of paper in a very satisfactory manner. For mechanically addressing, a portion of this

fibrous sheet enclosed in a frame of paper is placed into a special attachment that can be fitted to a typewriter and the wording can then be typed through the coating on the fibre as explained above. Stencils for addressing purposes are also made by cutting out small letters from stiff paper, by embossing metal plates, or perforating thin metal plates or paper. These perforated, cut or embossed stencils for addressing are made by special machines which stamp dies bearing letters or numerals with cutting edges, or punching surfaces as the case may be, against the stiff paper or thin metal. From these small stencils, the address is imprinted upon the desired place on a paper by means of other machines, either hand or power driven. The usual machine for this purpose holds a tray of these stencils and automatically carries each one over an inked pad where the ink is forced through the letters and printed upon the paper by the pressure of an arm that bears upon the stencil from above. This arm of the machine moves up when the pressure is released, and, if adjusted for the purpose, disposes of the used stencil by pushing it to one side; at the same time it moves forward the next stencil into its proper position on the pad. The addressing from embossed stencil addresses is performed by bringing down a plunger in which there is a rubber section that strikes the paper against an inked ribbon which covers the raised letters of the stencil.

STENDAL, stĕn'däl, Germany, a town in Prussia in the province of Saxony, on the Uchte, 35 miles north of Magdeburg. The cathedral, restored in 1893, contains archaeological and natural history collections of the region. It has courts of justice, a Roland pillar, two ancient gateways and a statue of Winckelmann, the art critic. It is an important railway centre. There are textile industries and large railroad shops, starch mills, brick yards, agricultural machine works and other factories. Pop. 27,263.

STENDHAL, stän-däl. See BEYLE, MARIE-HENRI; LA CHARTREUSE DE PARME; LE ROUGE ET LE NOIR.

STENIA, Turkey, a village on the European side of the Bosphorus, eight miles north of Constantinople, of which city it is a suburb. The name is probably an abbreviation of *Sosthenia* ("safety"), to which the Argonauts erected a temple in thanksgiving for their safe return from the Golden Fleece expedition. Constantine the Great converted the temple into a Christian church, and had the statue of the winged goddess in it transformed to represent the archangel Michael. In ancient times many sea-fights took place in the bay.

STENNESS, or **STENNIS**, Scotland, a loch in the Orkney Islands, a few miles northeast of Stromness, 14 miles in circumference. It is celebrated for two groups of prehistoric standing stones on its shores similar to those of Stonehenge. The large group, known as the Ring of Brogar, consists of 15 stones in an enclosure 340 feet in diameter. See STONES, STANDING.

STENO, stä'nō, Nicholas, Danish scientist: b. Copenhagen, 1638; d. Schwerin, Germany, 25 Nov. 1687. He was educated in medicine, made study of the anatomy of the time, wandered

about the Continent, finally settled at Florence, was made physician to Grand Duke Ferdinand II, but subsequently turned to a churchly career, was made a Roman Catholic bishop, and went to northern Germany as vicar-apostolic. He was the first to explain the nature of fossil animals, and in writing of the structure of the crust of the earth clearly described the stratification of rocks, and differentiated them as of mechanical, chemical and volcanic origin. Consult the article by Hughes in 'Nature' (1882).

STENOGRAPHY. See SHORTHAND.

STENOTAPHRUM. See GRASSES IN THE UNITED STATES.

STENTOR, in Greek history, the name of a herald in the Trojan War, famous for the loudness of his voice, which was said to equal that of 50 other men together; hence, a person having a very loud, strong voice.

STENTOR. See INFUSORIA.

STEP, Edward, English author: b. London, 11 Nov. 1855. He was editor of *Welcome* (1886-92); *Boys* (1892-94) and *Science Gossip* (1894-95). He has published 'Plant Life' (1880); 'By Seashore, Wood and Moorland' (1891); 'By Vocal Woods and Waters' (1894); 'Romance of Wildflowers' (1899); 'Shell Life' (1901), etc.

STEPHANITE ("brittle silver ore"), an orthorhombic metallic mineral, of iron-black color and streak; hardness 2 to 2.5; specific gravity, 6.3; brittle and opaque. It is a silver sulphantimonite, containing a large percentage of silver, and is an important ore of that metal in Austria, Germany, Mexico, Peru, Nevada, Idaho and elsewhere.

STEPHANOTIS, a genus of tropical asclepiadaceous climbing plants. They are twining shrubs, often reaching great heights, with deep-green, coriaceous, opposite leaves. The flowers are large, five parted, waxy and very fragrant, in axillary cymes. The corollas are funnel-shaped or salver-shaped, the limb being starlike, with overlapping lobes, and the tube long and cylindrical, but enlarged at the base and often again at the throat. *S. floribunda* is the evergreen greenhouse creeper, from Madagascar, famous for its waxy, fragrant flowers, appearing in spring and summer, and known by its generic name, or occasionally, as wax-flower or Madagascar jasmine.

STEPHANUS (Latin for *Estienne*, ä-tē-ën, *Etienne*), Charles, French scholar and printer: b. Paris, 1504; d. there, 1564. He abandoned the practice of medicine, in order to undertake the management of the Paris printing house which his brother Robert had abandoned on his retirement to Geneva. He was the author and printer of one of the first encyclopædias and gazetteers, 'Dictionnaire historique et poetique de toutes les nations, hommes, lieux, fleuves,' etc., (1553) and of 'Prædium Rusticum' (1554).

STEPHANUS (*Estienne*, *Etienne*), Henry (nephew of the preceding), French scholar and printer: b. Paris, 1528; d. Lyons, March, 1598. He was educated by the most accomplished scholars of his day and in 1551 accompanied his father to Geneva, where he acted as corrector of the press in his father's printing house. In 1554 he set up as an independent publisher and opened a new printing press with the assist-

ance of Huldreich Fugger of Augsburg. He subsequently spent some years in Italy, in England and in the Spanish Netherlands. His monumental work (*Thesaurus Linguae Græcæ*) did not bring him the returns he had counted upon, principally through the rival enterprise of John Scapula, who had been his proofreader, and had treacherously published himself a more handy and cheaper edition of the work. His troubles were increased by the death of his talented wife, Barbe de Wille (1581). Falling in commercial difficulties he became despondent, and was overtaken by sickness during a journey to Lyons; his reason became unsettled and he died in the hospital unattended by a friend. He was one of the most thorough Greek scholars of his time and his publications comprehended every relic of Greek literature then extant, and were distinguished by critical acumen, felicitous conjectural emendation, and exquisite typography. To him the scholars of Europe are indebted for 30 *éditiones principes* of classical authors, publications which have remained in many cases the standard text, and the basis for subsequent recensions. He wrote also several important works in the French language, among which may be mentioned '*Traité de la Conformité du Langue François avec le Grec*'; '*L'Introduction au Traité de la Conformité des Merveilles Anciennes avec les Modernes, où Traité préparatif à l'Apologie pour Hérodote*' (1566). Consult Feugère, '*Essai sur la vie et les ouvrages de Henri Estienne*' (1853).

STEPHANUS (Latinized form of Estienne, or Etienne), Robert, brother of Charles Stephanus (q.v.), French scholar and printer: b. Paris, 1503; d. Geneva, 7 Sept. 1559. He early devoted himself to a study of the ancient languages, Hebrew, Greek and Latin, and after the death of his father, Henry Stephanus the printer, he worked in the printing house with his stepfather Simon de Colines, but in 1529 opened an establishment of his own. Ten years later Francis I appointed him "Printer Royal in the Ancient Languages," but the hostility of the divines of the day was roused by his publication of certain works, especially the Bible, and drove him to Geneva (1551), where he joined the Reformed Church. In his house even the servants spoke in Latin. His publications amounted to 382 in all, and included the Bible, Old and New Testaments in the original; the Greek and especially the Latin classics, with prefaces and notes; grammars and school books. Francis I caused to be made for him the famous "royal type" (*characteres regii*). As an author he produced with the collaboration of Jean Thierry de Beauvais his valuable '*Thesaurus Linguae Latine*' (1531). Consult Crapelet, '*Robert Estienne, Imprimeur Royal*' (1839).

STEPHEN, stē'vën, Saint, one of the first seven deacons of Apostolic times. He was stoned to death by fanatic Jews, probably in the August of 32 or 33 A.D. In the Acts of the Apostles (chapter six and seven) an account of his character, works and death is given in some detail. He did "great wonders and miracles among the people"; he was "full of faith and power." While dying he prayed for those who were stoning him; and is considered the protomartyr, the earliest Christian witness

who died for his faith. In art he is represented in the vestments of a deacon; holding stones in his robe (the dalmatic) or in his hand; or with a stone in one hand, and a palm in the other. He is celebrated in the Greek Church on 27 December; in the Roman Catholic and Anglican Church on the 26th of that month.

STEPHEN, the name of ten popes, as follows:

STEPHEN I, Saint. He succeeded Lucius I in 253 and filled the papal chair till 257. He carried on a controversy with Cyprian of Carthage concerning the validity of the baptism of heretics, deciding in opposition to Cyprian that on being received into orthodoxy they must be rebaptized, which was not then the custom in Africa. He suffered martyrdom, and is honored as a saint, his day being 2 August.

STEPHEN II. He was chosen pope in March 752, but died four days later, before his enthronement and is sometimes erroneously omitted from the list of popes.

STEPHEN III. His pontificate lasted from 752 to 757. He sought the aid of Pepin the Short, against the Lombards who had overrun the exarchate of Ravenna. Pepin on defeating the Lombards gave the exarchate to the Pope, which marks the beginning of the temporal power of the papacy.

STEPHEN IV. He succeeded Saint Paul I in 768 and in a synod held in Rome in 769 sanctioned anew the veneration of relics and saints.

STEPHEN V. He succeeded Saint Leo IV in 816, but his pontificate came to an end the next year. During his pontificate the council of Aix-la-Chapelle was held, by which provisions were made for the foundations of cloistral schools.

STEPHEN VI. He succeeded Hadrian III in 885 and in a controversy with the Emperor Charles the Fat, occasioned by his consecration having occurred before Charles had given his sanction to the election, came off victorious. Guido of Spoleto and Berengarius of Friuli having contended for the throne of Italy Stephen supported the former and crowned him. His pontificate ended in 891 when he was succeeded by Formosus.

STEPHEN VII. In 896 he succeeded Boniface VI, caused the body of Pope Formosus, the predecessor of Boniface VI, to be exhumed and thrown into the Tiber on account of his having belonged to the opposite political party. He also canceled all the ordinances and consecrations of Pope Formosus. The next year he was imprisoned by his opponents and murdered in prison.

STEPHEN VIII. He succeeded Leo VI in the papal chair in 929 and was succeeded by John XI in 931.

STEPHEN IX. He was a relative of Emperor Otto I and his pontificate lasted from 939 to 942.

STEPHEN X. His rule lasted only from 1057 to 1058 but in that time the separation took place between the Roman and Greek churches. His pontificate is also noteworthy on account of the commencement of a series of internal reforms in the church which were probably due

to the influence of Hildebrand, afterward Gregory VII.

STEPHEN, king of England: b. Normandy, about 1100; d. 25 Oct. 1154. He was a son of Stephen, Count of Blois, by Adela, a daughter of William the Conqueror. His uncle, Henry I, gave him the earldom of Mortaigne, in Normandy, and large estates in England, in return for which he took the oath for securing the succession to Henry's daughter, the Empress Matilda. Upon the death of Henry, however, he claimed the Crown for himself (December 1135), and was crowned in London. His seat on the throne, by reason of the disaffection of many of the nobility, was very insecure, and in 1138 David of Scotland invaded England to secure the claims of his niece, but in the battle of the Standard was defeated by the northern barons (August 22). In the following year the empress herself landed in England with her half-brother, Robert, Earl of Gloucester, and a civil war ensued, in which Stephen was taken prisoner and Matilda acknowledged queen. Her conduct, however, excited an insurrection against her government; and, being shut up in Winchester Castle, she escaped with difficulty, while the Earl of Gloucester was taken prisoner. Stephen was exchanged for the earl, and the war was renewed. When Matilda retired to Normandy (about 1147) the contest was taken up by her son Henry. Finally the struggle was brought to an end in 1153 by the Treaty of Wallingford, in which it was agreed that Stephen should reign to his death, and that he should be succeeded by Henry.

STEPHEN, the name of several kings of Hungary from the 10th to the 13th century. **STEPHEN I**, Saint; d. 1038. He succeeded his father as Duke in 997, and was crowned first king of Hungary in 1000. He reformed the manners of his subjects, enacted excellent laws and introduced Christianity into his kingdom. Stephen was canonized and became the patron saint of Hungary. **STEPHEN II** succeeded his father Koloman in 1114. He invaded Poland and Austria, and marched into Russia, but was unsuccessful everywhere. He abdicated, retired to a monastery, and died in 1131. **STEPHEN III**; d. 4 March 1173. He was crowned king in 1161, but was almost immediately deposed by the nobles. He regained the Crown, however, in 1165 and reigned till his death. **STEPHEN IV**; d. Semlin, 1164. He ascended the throne in 1161. He was the uncle of Stephen III by whom he was defeated in 1163, soon after which he died. **STEPHEN V**; d. 1 Aug. 1272. He reigned two years only, 1270-72, but gained an illustrious name by his victories over Ottocar, king of Bohemia.

STEPHEN, Sir Leslie, English biographer and essayist: b. London, 28 Nov. 1832; d. there, 22 Feb. 1904. He was educated at Eton and Cambridge, and in 1883-84 was Clark lecturer on English literature at Cambridge. He edited *The Cornhill Magazine* 1871-82, and in the last-named year became editor of 'The Dictionary of National Biography,' which position he held for nine years, but continued to contribute to it till the work was completed, writing in all 378 biographies, an amount equal to three entire volumes and practically covering in the list the literary history of the 18th and

19th centuries. He was thoroughly conversant with the work of the theologians, philosophers and economists of those centuries and the outcome of his knowledge is seen in such works as 'History of English Thought in the 18th Century' (1876); 'Freethinking and Plain Speaking' (1873); 'Lives of Johnson' (1878); 'Pope' (1880); and 'Swift' (1882); 'An Agnostic's Apology' (1893); and 'The English Utilitarians' (1900), a work of the utmost importance. Still other works by him are 'The Playground of Europe' (1871), a record of Alpine experiences; 'Hours in a Library' (1874-79); 'Life of Sir James Fitzjames Stephen,' his brother, (1895); 'Social Rights and Duties' (1896); 'Studies of a Biographer' (1898); 'Thomas Hobbes' (1904). He was the warm friend of James Russell Lowell, visiting him more than once in this country, and was an appreciative admirer of the best in American literature and life. At the close of the Civil War he accomplished a great deal toward clearing away prejudice and misunderstandings between America and England in a pamphlet which contained a strong arraignment of the course of the London *Times* during the four years of war. His first wife, the youngest daughter of Thackeray, died in 1875. Stephen's religious attitude was that of the agnostic, but he was not aggressive. His greatest service to his time was in the 'Dictionary of National Biography.' For this work he was an ideal editor, his judgment determining not only the selection of subjects but the choice of writers, and he so carefully held them to their task that the work went regularly forward at the rate of four volumes a year. He was knighted in 1902.

STEPHEN BATHORI, king of Poland: b. Hungary, 1522; d. Grodno, Poland, 12 Dec. 1586. He was the second of the kings elected by the nobles of Poland, having been declared sovereign in 1575 to succeed Henry of Valois, who had become king of France. The royal prerogative, having been curtailed still further than in Henry's time, extended only over a small district adjacent to the king's estate, but Stephen wrested Livonia from Russia. He was the organizer of the first Cossack regiments and established the University of Wilna. See POLAND.

STEPHENS, sté'vénz, Alexander Hamilton, American statesman: b. near Crawfordsville, Wilkes County, Ga., 11 Feb. 1812; d. Atlanta, Ga., 4 March 1883. He was of Scotch-Irish ancestry; his grandfather, a youthful adherent of the House of Stuart, came to Pennsylvania in 1746, fought under Washington in the French and Indian War and in the Revolution, reaching the rank of captain; late in life he migrated to Georgia. His son, a schoolmaster of humble circumstances, was the father of Alexander and died when the latter was 15 years of age. Alexander was prepared for college by a Presbyterian minister, Rev. Alexander Hamilton Webster, and at the age of 16 he entered Franklin College (now the University of Georgia), a Presbyterian educational society paying his expenses with the understanding that he would become a minister. In 1832 Stephens was graduated with first honors, and having decided not to enter the ministry, he taught school for two years in order to pay

for his education. In 1834, after three months' preparation, he passed a brilliant examination and was admitted to the bar. As a lawyer he soon attained marked success and was then drawn into politics. An opponent of the policy of nullification he was one of the leaders in organizing the Whig party in Georgia; he was a member of the State legislature, 1836-42; in 1839 a delegate to the Charleston Commercial Convention; and in 1843 was elected to Congress on a general ticket. In 1838-39 he favored the annexation of Texas by joint resolution, but in 1844 he opposed Tyler's treaty of annexation and in the next year he framed the measure that secured the annexation. Though opposing Polk's policy in the Mexican War he considered the results of that war fortunate for the South. In Congress he fought the principle of the Wilmot Proviso, and was influential in bringing about the Compromise of 1850 which he considered a repeal of the Missouri Compromise. He opposed the strong "Southern Rights" movement that threatened to result in secession in 1850 and drafted the celebrated "Georgia platform" in which the State constitutional convention declared that while not entirely satisfied with the Compromise of 1850, Georgia was anxious to remain in the Union, though further encroachment upon her rights would result in secession. In 1852, Stephens, with other prominent Southern Whigs, signed a declaration that they would not support General Scott, the Whig nominee for President, because he did not approve the Compromise of 1850 as a final settlement of the questions involved. This stand broke up the Whig party in the South. Stephens and his colleague Toombs voted for Daniel Webster after he was dead. Holding the same views as Douglas in regard to the territories Stephens pushed through the House (1854) the Kansas-Nebraska bill. After 1854 he acted with the Democrats in opposing the formation of the American or Know-Nothing party out of the wreck of the Whig organization. Though he disliked Buchanan, Stephens supported his administration until 1859 when foreseeing a prolonged conflict over slavery he retired from Congress. In Congress he was a moderate pro-slavery man, not disposed to make extreme demands for theoretical rights. In 1860 he was on the Douglas electoral ticket and in Georgia he led the opposition to secession both before the people and in the Georgia convention, where, though asserting the right of the State to secede, he declared that conditions did not then justify a resort to that remedy. When his State seceded he acquiesced, was elected to the Confederate Provisional Congress by which he was chosen vice-president of the provisional government, and was sent to arrange a treaty between the Confederacy and Virginia. In 1862 he was elected vice-president under the permanent Constitution of the Confederate States. He was unable to reconcile his theories of government with conditions of war and was often at variance with President Davis on questions of war policy and State rights. In consequence the elements of opposition to the Davis administration gathered around him, but he had little influence during the war. In 1864 Stephens, his half brother, Linton Stephens, Robert Toombs and Joseph E.

Brown were leaders of the Georgia Peace party which declared that the Richmond government could make peace if Davis desired. In February 1865 Stephens headed the unsuccessful Confederate Peace Commission which met President Lincoln at Hampton Roads. Before the end of the war Stephens, discouraged, left Richmond and returned to his home in Georgia whence arose the report that he had deserted the Confederacy. He was arrested by the Federals in May 1865 and confined in Fort Warren in Boston Harbor until October when he was paroled. Stephens favored President Johnson's plan of restoration of the Union, saying that since the South had failed to preserve the Constitution out of the Union it should try again to save it within the Union. In 1866 he was elected to the United States Senate, but on account of the controversy over reconstruction, was refused a seat. He then turned his attention to writing a history of the sectional controversy, the first volume of which was published in 1867 and the second in 1870. In 1868 he was elected professor of history and political science in the University of Georgia, but on account of ill health, he was forced to decline. He edited the *Atlanta Sun* in 1871 in opposition to the election of Horace Greeley. Having lost nearly all his savings in this venture he undertook the instruction of a private law class. In 1871 he was an unsuccessful candidate for the United States Senate, but in 1874 he was elected to the lower house of Congress where he remained until 1882 when he resigned to become governor of Georgia. While in Congress he opposed the Civil Rights Bill of 1875, which aimed to extend certain social rights to the negro in the Southern States. He also objected to the methods of the Electoral Commission in 1877 and demanded that the fraudulent returns be rejected; but when Hayes was declared elected Stephens advised acquiescence. He was elected governor of Georgia in 1882 by a majority of 60,000 over his opponent, a popular Confederate soldier, and made an excellent governor but died before the end of his term. In personal appearance Stephens was small and thin, never weighing over 90 pounds. His health was always poor but his disposition was cheerful. He was never married. Children and negroes especially were fond of him, and to the latter he was a trusted friend. He never blamed them for the excesses of the carpet-bag governments. He believed in the fundamental and natural inequality of the races; and Southern society and government are still based on the principle of his Savannah speech of 1861 in which he declared that the Confederacy was founded on that inequality. He was a logical and effective speaker, without the arts of the popular orator. Whig or Democrat his political principles were the same; he was a Democrat of the school of Jefferson believing in State rights, State sovereignty, strong local government and the largest liberty of the individual compatible with good government. It was difficult for him to understand that changed economic and social conditions should be reflected in changed political institutions. Therefore in his views of government he was a legalist rather than a political scientist. He published 'A Consti-

tutional View of the War between the States' (1867-70); 'A School History of the United States' (1871); and a 'Compendium of the History of the United States' (1878-83). Though his 'Constitutional View' has great value as a historical document and all of his books are useful to show his views on politics and government, it cannot be said that he was successful as a historian, but rather as a lawyer, a politician and a statesman. Consult Johnston and Browne 'Life of A. H. Stephens' (1878; new ed., 1883); Cleveland, 'A. H. Stephens in Public and Private Life, with Letters and Speeches' (Philadelphia 1866); Pendleton, Lewis, 'Alexander H. Stephens' (ib. 1908); Trent, William P., 'Southern Statesmen of the Old Regime' (New York 1897); Avary, M. L. (ed.), 'Recollections of Alexander H. Stephens' (1910).

WALTER L. FLEMING,
Professor of History in Vanderbilt University.

STEPHENS, Henry Morse, American historian: b. Edinburgh, Scotland, 3 Oct. 1857. He was educated at Haileybury College, and Balliol College, Oxford, and was engaged in journalism 1880-92. After being lecturer on Indian history at Cambridge University 1892-94, he was called to the chair of modern European and English history at Cornell University in 1892, which he held till 1902. Since the date last named he has been professor of history at the University of California. He is the author of a much valued 'History of the French Revolution' (1886-92); and of 'The Story of Portugal' (1891); 'Albuquerque' (1892); 'Revolutionary Europe 1789-1815' (1893); 'Syllabus of a Course of Lectures on Modern European History 1600-1890' (1899).

STEPHENS, James, Irish revolutionist: b. Kilkenny, 1824; d. Dublin, 29 March 1901. At 21 he went to Dublin and joined the young Ireland party. He was wounded at the fight at Ballingarry, 29 June 1848. In the next 12 years he became prominently known as a Fenian, and as such exercised an enormous and despotic influence, and throughout showed remarkable dexterity in the disguises and characters he assumed on his visits to all parts of Ireland. In 1863 he founded the *Irish People*, published in Dublin. He visited the United States early in 1864 to attempt to overthrow the rival schemes formed there by patriots, and was arrested in Dublin on 10 November of the same year, 14 days later making his escape from Richmond Bridewell. He found his way to New York, where, in 1867, he was formally deposed by the Fenians, and fled to Paris. He was allowed to return to Ireland in 1891.

STEPHENS, James, Irish poet and novelist: b. County Dublin, February 1882. After many difficulties in early life he became a solicitor's clerk in Dublin, and in his leisure engaged in the writing of verse and fiction, showing marked ability in both fields. He has contributed to *Sinn Féin* and to the *Irish Review*. Author of 'Insurrections' (1909); 'The Hill of Visions' (1912); 'The Charwoman's Daughters' (1912); 'Here Are Ladies' (1913); 'The Rocky Road to Dublin' (1915); 'Songs from the Clay' (1915); 'Reincarnation' (1918), etc.

STEPHENS, James Burton, Australian poet: b. Barrowstowness, Scotland, 17 June 1835; d. 29 June 1902. He was educated at the University of Edinburgh; and was a travelling tutor from 1857 to 1860, when he went to Queensland where he ultimately secured an appointment in the Colonial Secretary's Office at Brisbane. Later he became Under-Secretary of the department. During his spare time he wrote much and is considered one of the foremost of Australian poets. Among his published works are 'Convict Once and Other Poems' (London 1871); 'Black Gin and Other Poems' (Melbourne 1873); 'Mute Discourse' (Brisbane 1878); 'Miscellaneous Poems' (London and Brisbane 1880); 'Tayctle or Bush Revels' (Brisbane 1892); 'Poetical Works' (Sidney 1902).

STEPHENS, John Lloyd, American author: b. Shrewsbury, N. J., 28 Nov. 1805; d. New York, 10 Oct. 1852. He was graduated at Columbia College in 1822; studied law, and practised for eight years at the bar in New York. He made an extended journey through Europe and the East, an account of which he published in fuller narrative form under the title 'Incidents of Travel in Egypt, Arabia, Petraea, and the Holy Land' (1837); and 'Incidents of Travel in Greece, Turkey, Russia and Poland' (1838). In 1839 he was sent by the United States government to negotiate a treaty with the government of Central America; and as the result of his experiences and investigations in that country published 'Incidents of Travel in Central America, Chiapas and Yucatan' (1841); and after further exploration 'Incidents of Travel in Yucatan' (1843). He was one of the organizers of the first Atlantic steam navigation company and one of the first presidents of the company which constructed a railway across the Isthmus of Panama, and superintended the construction.

STEPHENS, Uriah Smith, American labor reformer: b. near Cape May, N. J., 3 Aug. 1821; d. in Europe, 13 Feb. 1882. He was educated for the Baptist ministry, but became a tailor, which calling he followed until his death. He was a lover of books and a close student of economic affairs, and sought through speeches and letters to the press to reform labor conditions in the United States and to further the cause of Abolition. In 1869 he founded the Knights of Labor and afterward devoted himself to the upbuilding of that order. He became the first Grand Master Workman of its general assembly in 1878.

STEPHENS, William, American colonial governor: b. Boscombe, Isle of Wight, 28 Jan. 1671; d. Georgia, August 1753. He was graduated at Cambridge in 1688, and before coming to America represented the Isle of Wight in Parliament. In 1736 he made the acquaintance of James Oglethorpe in South Carolina, and in the following year went to Georgia, where he was successful as a planter, and rose to prominence in the new community. In 1743 he was made president of the county of Savannah, and later governor of the entire colony. His administration lasted until 1750, when he resigned. He wrote 'A Journal of the Proceedings of Georgia from October 20, 1737,' a valuable historical work, but few complete

GEORGE STEPHENSON

First to apply the locomotive steam engine to railways for passenger traffic

copies of which remain. 'The Castle-builder, or the History of William Stephens of the Isle of Wight' (2d ed. 1759) is a biography by his son.

STEPHENS, William Richard Wood, English Anglican clergyman and author: b. Gloucestershire, 5 Oct. 1839; d. Winchester, 22 Dec. 1902. He was educated at Oxford, took orders in the Established Church, was vicar of Mid-Lavant, Sussex, 1870-73, rector of Woolbeding, Sussex, 1876-94, and dean of Winchester from the latter date. He published 'Saint Chrysostom: his Life and Times' (1872); 'Christianity and Islam' (1877); 'Hildebrand: his Life and Times' (1888); 'Life and Letters of Edward Augustus Freeman,' a work of much value (1895); 'The English Church from the Norman Conquest to Edward I' (1901).

STEPHENSON, stē'vən-sŏn, George, English inventor: b. Wylam, near Newcastle, 9 June 1781; d. near Chesterfield, 12 Aug. 1848. He was successively assistant fireman, fireman and brakeman in a colliery, in 1802 was made engineman at Willington Ballast Hill, in 1808 took with two others the contract to operate the engines at Killingworth pit, and in 1812 was appointed engine-wright there. The application of steam power to locomotive engines had for some time engaged the attention of scientific men. Stephenson eagerly devoted himself to the working out of the idea, and having established an extended reputation for soundness of judgment and engineering skill he was supplied by Lord Ravensworth with the means of constructing a locomotive engine, which was placed, 25 July 1814, on the colliery tramway, and drew eight loaded wagons at the rate of four miles an hour. Though thus partially successful, Stephenson saw that more was needed to make this mode of conveyance advantageous, and he accordingly invented the "steam blast," which enabled him to double his rate of speed, and in 1815 he took out a patent for, and constructed, an engine which up to the present day (under certain modifications and improvements) has, like Watt's steam engine, continued as a model in the construction of locomotives. In this same year he devised a safety-lamp, the Geordie, for miners, which was produced prior to and altogether independent of the better-known invention of Sir Humphry Davy, and is still employed in preference to the latter in some parts of Northumberland. The following year he took out a patent for an improved form of rail and chair. In 1819 he was employed to construct a railway for the proprietors of the Hetton Colliery, and in 1822 the Stockton and Darlington line for Pease, its leading promoter, who appointed him resident engineer, with an annual salary of £300. The line was opened 27 Sept. 1825, the engine being driven by Stephenson himself, and drawing 38 carriages, with a total weight of about 90 tons, at a rate of from 12 to 16 miles an hour. This was the first steam railway in Great Britain on which passengers were conveyed as well as goods. At this period a copartnership was formed between Pease and Stephenson for the establishment of a locomotive manufactory at Newcastle, which was long the only work of the kind in the kingdom, and rapidly increased in extent and importance. The scheme of con-

structing a railway between Liverpool and Manchester had been set on foot in 1824, but the opposition to it, both in and out of Parliament, was so strong that it had to be temporarily abandoned. The bill was passed, however, on a second application, and the work commenced in 1826. After overcoming many difficulties, one of the greatest being the carrying of the line over Chatmoss, the railway was opened on 15 Sept. 1830. The results of the undertaking were most triumphant for Stephenson, and it proved the commencement of the British system of railroad transit. For 10 years subsequent to this there was scarcely a line of railway opened in Great Britain with the construction of which Stephenson was not concerned. In 1840 he resigned most of his appointments, and settled at Tapton, in Derbyshire, where he took in hand the working of the Clay Cross Collieries, leaving the extension of the railway system to be carried out by his son Robert (q.v.). He still, however, remained connected either as engineer or otherwise with several lines, made professional journeys to Spain and Belgium, and was created a knight of the latter country by King Leopold. He also took a considerable interest in mechanics' institutes, and was the founder and president of the Institution of Mechanical Engineers at Birmingham. George Stephenson may be regarded as an embodiment of the sturdy and energetic spirit which has raised the British nation to its high position industrially among the other countries of the world, and enabled it to effect such triumphs in enterprise. The standard authority is the 'Life' by Smiles as revised by that author for Vol. III of his 'Lives of the Engineers' (1862). See LOCOMOTIVE.

STEPHENSON, Robert, English civil engineer: b. Willington Quay, near Newcastle, 16 Oct. 1803; d. London, 12 Oct. 1859. He was the son of George Stephenson (q.v.). In 1822 he studied at Edinburgh University. The elder Stephenson having shortly after this engaged in the locomotive manufactory at Newcastle in conjunction with Pease, Robert became his apprentice in 1823, but his health giving way after two years, he accepted an engagement to examine the South American mines, returning to England in 1827 by way of the United States and Canada. Not long after his return he assisted his father and Henry Booth in the construction of the locomotive (the "Rocket") which gained the prize of £500 offered by the directors of the Liverpool and Manchester Railroad for the best railway engine. The next great work on which he was engaged was the construction of the London and Birmingham Railway, the first railway into London, of which he was appointed engineer. The first sod of the line was cut at Chalk Farm in June 1834, and the railway opened to the public in September 1838. Much of his attention was given to the superintendence of the manufactory at Newcastle, and he made frequent professional journeys abroad, laying out lines of railway in Switzerland, Germany and other parts of the Continent and likewise in Canada, Egypt and India. One of the most brilliant proofs of his engineering skill is displayed in the system of railway bridges and viaducts constructed under his directions. Among these may be mentioned more especially

the high-level bridge at Newcastle, the Victoria bridge at Berwick, the tubular bridges, of which he was the inventor, as exemplified in those over the Conway and the Nile, and the still more wondrous erections of the Britannia bridge over the Menai Straits, and the Victoria bridge over the Saint Lawrence. He introduced the tubular girder system in the building of wrought-iron bridges. He took a considerable interest in public affairs, and from 1847 represented the borough of Whitby in Parliament. He served a term as president of the Institution of Civil Engineers, and his remains lie in Westminster Abbey. Consult Smiles, 'Lives of the Engineers' (Vol. III, 1862).

STEPHENSON, Mich., township and village in Menominee County, on a tributary of the Menominee River, 168 miles north of Milwaukee, Wis., on the Chicago and Northwestern Railroad. There are flour and lumber mills and a sugar beet industry. Pop. township, 3,000.

STEPHENSON'S DEPOT (CARTER'S FARM), Engagement at. On 19 July 1864 General Averell with 1,000 cavalry, 1,350 infantry and two batteries, marched up the Valley Pike from Martinsburg, W. Va., drove the Confederate cavalry from Darkesville toward Winchester, and halted near Stephenson's Depot, about six miles from Winchester. This placed him in rear of Early, who was at Berryville, who immediately retreated toward Strasburg, first sending Ramseur's division of infantry and two batteries to Winchester to support the cavalry brigades of Jackson and Vaughan, and check Averell's advance. On the morning of the 20th Averell, who had received a reinforcement of 300 cavalry, raising his force to about 2,800, resumed his march toward Winchester, in line of battle, to resist a sudden attack or to make one. A regiment of infantry was deployed on either side of the road, with skirmishers in advance, another regiment marched on each side in column in rear of the right and left flanks, artillery in the centre, on the road, and a regiment of cavalry on each flank. Three miles north of Winchester, on Carter's Farm, Ramseur was encountered, moving with intent to capture Averell, whose force had been reported as a regiment of cavalry and one of infantry. Ramseur opened fire with four guns and demonstrated with his cavalry on both flanks, under cover of which he formed line, Johnson's brigade on his right, Hoke's on the left, with Pegram's in reserve. Averell deployed his entire command in one line, withdrew his skirmishers, opened fire from his 12 guns, and, without pausing, sent in all his cavalry and infantry, drove in the Confederate cavalry, broke Ramseur's left, held by Hoke, which fled in disorder, followed by the remainder of the division to near Winchester, where Averell's immediate pursuit was checked by Jackson's cavalry. Averell captured four guns and about 280 wounded and unwounded prisoners, among them Generals Lewis and Lilly, wounded. Ramseur had 73 killed and 130 wounded. Averell had 53 killed, 155 wounded and six missing. Informed that a large force was gathering in his front, Averell established a strong picket-line and fell back two miles. On the

morning of the 21st he entered Winchester unopposed, the Confederates having retreated toward Strasburg. On the 22d he was joined by Crook and next day both fought the battle of Kernstown (q.v.).

STEPNEY, a metropolitan borough of London, England, within the Parliamentary borough of Tower Hamlets. Area, 1,766 acres. The borough is typically east end, containing the districts of Whitechapel, Limehouse and Mile End, abounding in the most depressing poverty. Saint Katherine's and the London docks, the Tower of London and the Royal Mint, are situated within the borough. The People's Palace, Toynbee Hall, the London Hospital, Whitechapel and Dr. Bernardo's Homes are some of its institutions. Spitalfields is historically famous as a silk-weaving centre. There is a large foreign population, numbering about 53,060, of which 43,925 were natives of Russia or Russian Poland, out of a total of 63,105 of these nationalities in London. Pop. about 279,804.

STEPNIAK, stěp'nyāk, **Sergius** (real name SERGIUS MICHAELOVITCH KRAVCHINSKI), Russian revolutionist and author: b. southern Russia, 1852; d. London, 23 Dec. 1895. After a liberal education, he identified himself with the revolutionary movement, was arrested in 1874 but released, and in 1880, on account of his advocacy of the "terrorist" policy, was compelled to leave the country. He went to Switzerland and later to England, became identified with the Socialists there and with the Social Democrats of the Continent, and wrote and lectured (also in the United States) on the liberalization of Russia. Among his books on conditions and methods were 'Underground Russia' (1882) and 'King Stork and King Log' (1896). His views altered from violent to constitutional means in securing popular freedom.

STEPPES, stěps, Russia, a Tatar term employed geographically to denote those extensive tracts of land which, beginning at the Dnieper, extend along the southeast of Russia, round the Caspian and Aral seas, between the Ural and Altai mountains, and occupy a considerable portion of Siberia. These steppes present wide, treeless, monotonous tracts, which are covered with rough grass and shrubs during the short spring season, but soon become arid deserts owing to the drought of summer, and in winter are wastes of snow. Though they are all open, flat and treeless, they differ considerably in aspect according to the nature of the soil of which they are composed; some tracts consisting of deep, black earth, clothed with shrubs and grasses; others of hard, sandy clay and sterile; and others again of sand or rocky shingle and only here and there dotted with vegetation. This applies, however, only to the spring and early summer; for during the summer droughts all are alike desert save round the springs and streamlets, and during winter, which comes on in October, the whole is one exposed and inhospitable snow-waste. The Siberian plain, as might be expected from its extent, is of a more varied character, consisting of low-lying tundras, or black, swampy peat mosses, of broad undulating steppes and partially wooded uplands;

but the tundras and wooded lands are scarcely included in the steppes proper. From June till the middle of August the tundras are thawed to a small depth, the steppes are scantily covered with grass and mosses, the banks of the great rivers are green with the birch and pine and immense herds of horses and cattle give animation to the scene. In winter fearful storms rage and the dry snow is driven by the gale with a violence which neither man nor animals can resist.

STERCULIACEÆ, stêr-kû-lî-â'sê-ê, a family of dicotyledonous plants closely allied to the *Malvaceæ*, from which they are distinguished by the two-celled anthers. There are about 30 genera and 150 species, which comprise tropical and sub-tropical herbs, shrubs and trees with alternate, entire, lobed or digitately compound leaves, and generally axillary flowers which are often large and beautiful. They are also characterized by their mucilaginous qualities. Many are of economic importance, being used for food and for various other purposes. One of the best known species cultivated in the United States is the Chinese parasol tree, or Japanese varnish tree (*Sterculia platyfolia*), which is very popular in the southern States upon lawns and is often found wild. In California *S. diversifolia* and *S. acerifolia* are popularly planted upon lawns and in streets for their shade and showy flowers, which in the former species are yellowish-white or greenish-red, and in the latter brilliant scarlet, hence a popular name "flame-tree." Both are natives of Australia.

STERE, stâr, the French unit for solid measure, equal to a cubic metre or 35.3156 cubic feet. See WEIGHTS AND MEASURES.

STEREO-CHEMISTRY (Greek, *stereos*, "solid"). In the development of the science of chemistry, it was discovered that two or more compounds may have the same empirical formulæ and yet differ from one another in chemical and physical properties to a marked degree. Resorcin, pyrocatechin and hydroquinone, for example, all have the empirical formula $C_6H_4(OH)_2$, and yet they are distinctly different substances. Most cases of this kind are explainable by supposing that the constituent atoms are linked together in different ways in the several compounds; the compounds themselves being called "isomers," and the phenomenon "isomerism." (See ISOMERISM; AROMATIC COMPOUNDS; FATTY COMPOUNDS). The arrangement of the atoms in such compounds has been investigated in many of these cases, and "constitutional formulæ" have been devised for the purpose of representing the internal structures of their molecules. Compounds have been found to exist, however, which apparently have the same constitutional formulæ and which resemble one another very closely indeed in most respects, but which nevertheless exhibit certain differences in physical and chemical properties, so that they cannot be regarded as absolutely identical. It is the province of stereo-chemistry to investigate such bodies and to show how it is possible to reconcile their exceedingly close similarity with the existence of recognizable differences in certain respects. Isomerism of the kind here contemplated is commonly called "optical isomerism," from the

fact that the bodies that manifest it differ with respect to their action upon polarized light. It has long been known that certain crystals possess the power of rotating the plane of polarization of the light that they transmit. It is also known that the crystals of a substance that affects light in this manner may sometimes be obtained in two slightly different forms, which possess symmetry of the same kind, and whose corresponding angles are equal, but which differ in the same manner as a man's right hand differs from his left one, or as the image of an object as seen in a mirror differs from the object itself. A pair of crystals that differ only in this respect are said to be "enantiomorphous," and if one of them rotates the plane of polarization to the right, the other, when similarly placed, will rotate it to the left; the angle of rotation being the same in each case, if the crystals are of equal thickness. If two such enantiomorphous crystals of the same substance are melted or dissolved, the respective fluids that are obtained from them are commonly found to be identical with each other in all respects, so that if they affect the plane of polarization at all, they rotate it in the same direction, and by the same amount. It is plain that in cases of this sort the differences between the original crystals are of a purely physical nature, depending only upon the way in which the molecules of the substance are grouped, and not at all upon the internal structure of those molecules. In other words, two enantiomorphous crystals are to be regarded as composed of identically the same chemical substance, if they differ only in their optical properties, and become identical in all respects upon being melted or dissolved. Stereo-chemistry has nothing to do with substances of this sort, which are not to be regarded as isomeric in any sense. Stereo-chemistry deals

FIG. 1.

FIG. 2.

entirely with substances whose optical differences are manifested even in the liquid state, and hence are to be attributed to internal differences in the molecules rather than to mere differences in the grouping of the molecules among themselves.

As a simple example of optical isomerism, the case of lactic acid and its isomers may be cited. Lactic acid (which occurs in sour milk, and which may be extracted in the form of a syrupy liquid) has no effect upon polarized light; but sarcosyllactic acid (which occurs in the juice of flesh) rotates the plane of polarization to the right, and yet its chemical properties are practically identical with those of common lactic acid. A third acid, known as "lævo-rotatory lactic acid," has been prepared, which is almost indistinguishable from the two foregoing substances so far as its chemical properties are concerned, but which rotates

the plane of polarization to the left. The chemical properties of all three agree with the constitutional formula $\text{CH}_3\text{CH}(\text{OH})\text{COOH}$; and yet they cannot be regarded as chemically identical. When polarized light is passed through equal thicknesses of equally concentrated solutions of sarcolactic and lævo-rotatory lactic acids, the plane of polarization is rotated in opposite directions, but by the same amount; and when equal quantities of sarcolactic and lævo-rotatory lactic acids are mixed, the mixture has no effect upon the plane of polarization, and (in fact) the mixture cannot be distinguished from ordinary lactic acid in any way. These general characteristics are manifested by all of the simpler optical isomers. They occur in pairs (or "twins"), one member of which rotates the plane of polarization to the right, while the other rotates it equally to the left. A third isomer also exists, which is composed of equal parts of the two optically active ones, and which is, therefore, itself inactive. The inactive member of the group is often called the "racemic" modification, the name being derived

FIG. 3.

FIG. 4.

from racemic acid, which is an optically inactive mixture of dextro-rotatory and lævo-rotatory tartaric acids. (This statement, it is to be observed, applies only to the simpler cases of optical isomerism. For a more general statement, applicable in all cases, see below).

In 1874 Le Bel and van't Hoff, simultaneously and independently, pointed out that all known compounds which manifest optical isomerism contain at least one "asymmetrical" (or unsymmetrical) central atom. In most of the known cases, this central, asymmetrical atom is a carbon atom; but a few cases are now known in which it is nitrogen. The chemistry of asymmetrical nitrogen compounds is still in its infancy, however, and hence in the present article attention will be confined solely to the asymmetrical carbon atoms; and we shall first treat of compounds in which only one such atom is present.

Carbon is a tetravalent substance, having four valencies (or bonds); and it has been well established (especially by the exhaustive researches of L. Henry) that these four valencies of carbon are all alike, so that if one atom of hydrogen in methane (CH_4), for example, be replaced by one atom of any other monovalent substance, such as chlorine, the resulting compound is precisely the same, whichever of the hydrogen atoms is so replaced. The fundamental discovery of Le Bel and van't Hoff was that the simplest class of the substances which exhibit optical isomerism may be regarded as derived from methane, by substituting, for at least three of the hydrogen atoms that it contains, an equal number of monovalent atoms or radicals, no two of which are alike; so that the resulting compound consists of a central

nucleus of carbon, each of whose valencies is satisfied by a different atom or radical. A carbon atom whose valencies are satisfied in this way is called an "asymmetrical" carbon atom.

FIG. 5.—Maleic Acid.

FIG. 6.—Fumaric Acid.

In the case of the various lactic acids which have already been cited, one of the fundamental hydrogen atoms of the methane remains undisturbed, while the other three are respectively replaced by OH, CH_3 and COOH. The structural formula of any one of these acids

may, therefore, be written $\text{OH}-\text{C}-\text{COOH}$.

The central carbon atom is here the "asymmetric" atom, since its four bonds are satisfied by four unlike univalent radicals or atoms. From the admitted equality and similarity of the four carbon bonds, it appears to be inadmissible to suppose that the nature of the compound that is represented above can depend (for example) upon whether the COOH group is opposite the OH group, or adjacent to it. Le Bel and van't Hoff, however, suggested that we should think of the four carbon bonds, not as four lines radiating out from the carbon atom in some one plane, but as lines radiating out from the carbon atoms in space, in four symmetrically related directions. The carbon atom being represented by a given point in space, for example, we are to think of the four bonds that it has as corresponding to the four vertices of an equilateral tetrahedron, having the carbon atom at its centre. For the sake of further illustration, let us suppose that we are looking down upon one of the vertices of such an equilateral tetrahedron, as suggested in Figs. 1 and 2; and let us represent the four dissimilar radicals (or atoms) by which the four bonds of the carbon are satisfied, by the letters A, B, D and E. We may suppose that in one of the optically active isomers these four radicals are disposed as in Fig. 1, and in the other as represented in Fig. 2. It is evident that two substances having such similar constitutions would be chemically so similar that it would be difficult to distinguish them by any ordinary test; and yet it is evident that they are not identical, since it will be found to be impossible to superpose either of these tetrahedra upon the other one, in such a way as to bring into coincidence all the vertices that carry similar radicals (or atoms). In fact, these two tetrahedra resemble each other enantiomorphically, just as the image of an object in a mirror resembles the

object itself; and superposition is, therefore, impossible. The constitution of sarcolactic acid, according to this general scheme, might be represented as in Fig. 3, that of *lævo*-rotatory lactic acid being then represented as in Fig. 4. The central dot by which we have here represented the asymmetric carbon atom in each of these compounds is usually omitted from diagrams of this sort, the presence of this atom being sufficiently represented by the tetrahedron itself.

The name "stereo-chemistry" has reference to the use of a solid diagram for representing the constitutions of the compounds with which it is concerned; and the ideas which have been presented above are capable of being expanded into a general theory of the constitution of carbon compounds. The first successful attempt at the formulation of a theory of this sort was made by van't Hoff, in 1878. In this theory (which includes the explanation of isomerism of all kinds by the geometric relations of the solid diagrams that are used, and which is, therefore, often called the theory of "geometrical isomerism"), each carbon atom in a given compound is supposed to be represented by a separate tetrahedron; though in the practical applications of the theory it is customary to omit all the tetrahedra except those that relate to the central carbon atom, or to those which are of special or fundamental importance. When two carbon atoms are united by a single bond, their corresponding tetrahedra are supposed to be united in such a way that they are symmetrically situated, with one vertex in common; when they are united by two bonds, they are supposed to be symmetrically situated, with one edge in common; and when they are united by three bonds, they are supposed to have one entire face in common. In the case of the triple bond, the theory has no special interest; for in this case theory does not indicate any possibility of isomerism, nor has experiment revealed any case of this kind in which isomerism exists. The use of a solid diagram for illustrating the isomerism of compounds containing two carbon atoms united by a double bond will be understood from Figs. 5 and 6, which correspond, respectively, to maleic and fumaric acids. (See MALEIC ACID). There is no optical isomerism in the case of these compounds; this circumstance being explained, according to the theory of geometrical isomerism, by the fact that the points of attachment of the hydrogen atoms and the COOH groups are in each case all in the same plane. Moreover there is no asymmetric carbon atom in either case, because if the tetrahedra were separated, they could be turned so as to be perfectly superposable. The relative distances between the points of attachment of corresponding radicals (or atoms) is not the same in Fig. 5 as in Fig. 6, and hence it is to be expected that the isomers that these diagrams represent will behave differently with respect to solubility, melting point, boiling point and in other respects also, including the facility with which they will react with other substances. It may be noted, in passing, that the atoms and radicals shown in Figs. 5 and 6 admit of still another arrangement, in which both of the hydrogen atoms are attached to one of the tetrahedra, and both of the carboxyl

groups (COOH) are attached to the other one. The substance having this structure is actually known, and is called "methylene-malonic acid." Its properties are quite different, however, from those of maleic and fumaric acids, as might be inferred from the markedly different character of its structural diagram.

Tartaric acid affords an interesting example in stereo-chemistry, not only on account of its structure, but also because it was upon this acid and its modifications that Pasteur performed the classical experiments which led (1860) to the development of the methods that are now used for the separation of optical isomers. The constitutional formula for tartaric acid as ordinarily written is

Each of the two central carbon atoms is here asymmetric, because each has its four bonds satisfied by four different substances. In the solid diagram for representing the structure of tartaric acid we shall, therefore, have to make use of two tetrahedra; and since the two nuclear carbon atoms are directly united by one bond, their corresponding tetrahedra will be symmetrically situated, and will have one vertex in common. In attaching the hydrogen, the hydroxyl (OH) and the carboxyl (COOH) to the vertices of the tetrahedra, we may adopt any one of three essentially different arrangements, for representing the relations expressed by the foregoing structural formula. These are shown in Figs. 7, 8 and 9. It will be observed, in Fig. 7, that the radicals and atoms that are attached to the vertices are so situated that the two tetrahedra would be superposable in all respects, if they were separated from each other. According to stereo-chemical theory, this signifies that the compound that Fig. 7 represents will rotate the plane of polarized light by an amount equal to the sum of the effects of the two constituent asymmetrical tetrahedra. Turning now to Fig. 8, it will be seen that the two tetrahedra in this diagram also admit of superposition upon themselves, if they are separated; and hence the compound that this diagram represents will also rotate the plane of polarization by an amount that is equal to the sum of the effects that are due to its two constituent tetrahedra. It will be noted, however, that neither of the tetrahedra in Fig. 8 can be superposed upon either of those in Fig. 7; and this fact (when taken in connection with the identity of the two types of tetrahedra in all other respects) signifies that the compounds that are represented by Figs. 7 and 8 will rotate the plane of polarization by equal amounts, but in opposite directions. Fig. 7 may, therefore, be taken to represent dextro-rotary tartaric acid, while Fig. 8 represents the *lævo*-rotatory variety of the same substance. In the configuration shown in Fig. 9, it will be observed that the two tetrahedra, if separated, cannot be superposed; for they are enantiomorphic, or respectively right-handed and left-handed. According to the theories of stereo-chemistry, one

of these tetrahedra tends to cause the plane of polarization of polarized light to rotate to the right, while the other tends to rotate it by an equal amount to the left; and hence the substance, as a whole, will be optically inactive. In addition to these three varieties of tartaric acid (all of which are known and can be actually prepared), there is a fourth variety which is optically inactive, but which is not really chemically distinct from the varieties that have been described. This is known as "racemic acid," and it consists of a mere mixture of equal parts of the dextro-rotatory and lævo-rotatory acids.

exceedingly close, but certain slight differences are nevertheless observable, and these render the separation of the isomers possible. Special methods of separation may be adopted in special cases; but the three general methods that we have, and which are due to Pasteur, are as follows: (1) The mixed isomers are caused to combine with some other substance, whose isomeric compounds exhibit differences in melting point, solubility or crystallization; and when the compounds have been separated by the usual methods applicable in such cases, they are separately decomposed so as to liberate the isomers of the original substance again.

FIG. 8.

FIG. 9.

Constitution of the Isomers of Tartaric Acid.

The general facts of optical isomerism are thus stated by Nernst: (1) No compounds are optically active in the amorphous, homogeneous state (whether solid, liquid or gaseous), save those which contain one or more asymmetrical carbon atoms in the molecule. (2) If several asymmetrical carbon atoms exist in the molecule,—for example, *two*,—then the rotations that are due to these respective atoms may be denoted by A and B, and the following combinations are possible, in the isomeric forms which the substance may exhibit:

The two substances corresponding to the first horizontal row are called "isomeric twins," since they produce equal rotations, but in opposite directions. If the compound has *n* asymmetrical carbon atoms, then the number of optical isomers is $2n$, and two of these must be twins. (3) All compounds which contain asymmetric carbon atoms are not necessarily optically active; for the rotation that they produce may be too small to admit of detection; or the internal structure may be such as to produce internal optical compensation, as in the case of Fig. 9; or the compound may be a mixture of the dextro-rotatory and lævo-rotatory isomers, as in the case of racemic acid, already cited.
